To so many fine memories of my mother Ashraf, my father
Mohammad, and my brother Mohsen, for their uncompromising
belief in the power of education.

About the Editor-in-Chief

Hossein Bidgoli, Ph.D., is professor of Management Information Systems at California State University. Dr. Bidgoli helped set up the first PC lab in the United States. He is the author of 43 textbooks, 27 manuals, and over five dozen technical articles and papers on various aspects of computer applications, information systems and network security, e-commerce, and decision support systems published and presented throughout the world. Dr. Bidgoli also serves as the editor-in-chief of *The Internet*

Encyclopedia, *The Handbook of Information Security*, and *The Encyclopedia of Information Systems*.

The Encyclopedia of Information Systems was the recipient of one of the Library Journal's Best Reference Sources for 2002 and *The Internet Encyclopedia* was recipient of one of the PSP Awards (Professional and Scholarly Publishing), 2004. Dr. Bidgoli was selected as the California State University, Bakersfield's 2001–2002 Professor of the Year.

Contents

Contributors	xvii	Video Compression	227
Preface	xxiii	<i>Immanuel Freedman</i>	
Guide to The Handbook of Computer Networks	xxvi	Speech and Audio Compression	268
Reviewers List	1237	<i>Peter Kroon</i>	
Index	1247	Multimedia Streaming	282
		<i>Nabil J. Sarhan</i>	
Volume I: Key Concepts, Data Transmission, and Digital and Optical Networks		High-Definition Television	293
		<i>Jim Krause</i>	
Part 1: Key Concepts		Part 2: Hardware, Media, and Data Transmission	
The Telecommunications Industry	3	Modems	309
<i>David G. Loomis</i>		<i>Darren B. Nicholson and Jennifer A. Nicholson</i>	
Data Communications Basics	19	Conducted Communications Media	320
<i>Hossein Bidgoli</i>		<i>Thomas L. Pigg</i>	
Data-Link Layer Protocols	30	Wireless Channels	334
<i>Stefan Joe-Yen and Chadwick Sessions</i>		<i>Okechukwu C. Ugweje</i>	
Network Layer Protocols	40	Sources of Errors, Prevention, Detection, and Correction	352
<i>Muhannad Harrim, Mohamed El-Wakil, and Ala Al-Fuqaha</i>		<i>Syed H. Murshid and Azhar M. Khayrattee</i>	
Transport Layer Protocols	63	Routers	364
<i>Vassilis Tsaoussidis</i>		<i>Min Song</i>	
Session, Presentation, and Application Layer Protocols	76	Switches	375
<i>Chadwick Sessions</i>		<i>Min Song</i>	
Digital Transmission	84	Bridges	390
<i>Marvi Teixeira and Viktor Zaharov</i>		<i>Zartash Afzal Uzmi and Tariq Mahmood Jadoon</i>	
Analog Transmission	102	Pulse Amplitude Modulation	403
<i>Hamidreza Saligheh, Joonhyuk Kang, Jaehak Chung, and Vahid Tarokh</i>		<i>Muneo Fukaishi</i>	
Voice Communications Systems: KTS, PBX, Centrex, and ACD	115	Frequency and Phase Modulation	414
<i>Hassan Ibrahim</i>		<i>Albert Lozano-Nieto</i>	
Messaging Systems: Facsimile and Voice Processing	127	Carrierless Amplitude Phase Modulation	426
<i>Albert K.S. Wong, Nan Zhang, and Xu Yan</i>		<i>Tim Collins</i>	
Public Switched Telephone Network	158	Minimum Shift Keying	438
<i>Jingxuan Liu and Nirwan Ansari</i>		<i>Tao Jiang</i>	
Information Theory	178	Optical Differential Phase Shift Keying	455
<i>David Blockus and Mark Stamp</i>		<i>Xiang Liu</i>	
Data Compression	199	DMT Modulation	473
<i>Chang-Su Kim and C.C. Jay Kuo</i>		<i>Stephan Pfletschinger</i>	
Image Compression	212	Pulse Position Modulation	492
<i>Alfred Mertins</i>		<i>Jon Hamkins</i>	

Digital Phase Modulation and Demodulation	509	Fiber-Optic Filters and Multiplexers	850
<i>Zartash Afzal Uzmi</i>		<i>Hamid Hemmati</i>	
Line Coding	522	Optical Solitons	861
<i>Asim Loan</i>		<i>Natalia M. Litchinitser</i>	
Spread Spectrum	538	Synchronous Optical Code Division Multiplexing Systems	885
<i>Murad Hizlan</i>		<i>Hideyuki Sotobayashi</i>	
Frequency Division Multiplexing	553	Free-Space Optics	900
<i>Zhu Liu</i>		<i>John Liu and Mark Schaefer</i>	
Time Division Multiplexing	568	Optical Switching Techniques in WDM Optical Networks	909
<i>William A. Shay</i>		<i>Amor Lazzez, Nouredine Boudriga, and Mohammad S. Obaidat</i>	
Statistical Time Division Multiplexing	579	SONET and SDH Networks	929
<i>Kavitha Chandra</i>		<i>M. Farooque Mesiya</i>	
Orthogonal Frequency Division Multiplexing	591	Passive Optical Networks for Broadband Access	948
<i>Shinsuke Hara</i>		<i>Nirwan Ansari and Yuanqiu Luo</i>	
Wavelength Division Multiplexing	606		
<i>Yassine Khelifi, Nouredine Boudriga, and Mohammad S. Obaidat</i>			
 Part 3: Digital and Optical Networks		 Volume II: LANs, MANs, WANs, The Internet, and Global, Cellular, and Wireless Networks	
Digital Communication Basics	629	Part 1: LANs, MANs, and WANs	
<i>Robert W. Heath and Atul A. Salvekar</i>		Local Area Networks	3
Digital Radio Broadcasting	642	<i>Wayne C. Summers</i>	
<i>Zhuojun Joyce Chen</i>		Ethernet LANs	19
Spread Spectrum Signals for Digital Communications	675	<i>William Stallings</i>	
<i>Filippo Giannetti and Marco Luise</i>		Token Ring LANs	27
Optical Fiber Communications	692	<i>Norman C. Strole, Werner Bux, and Robert D. Love</i>	
<i>Habib Hamam and Sghaier Guizani</i>		Optical Fiber LANs	40
Optical Transmitters, Receivers, and Noise	708	<i>Mo Adda, Amanda Peart, and Jau Ming Chew</i>	
<i>Ken Pedrotti</i>		Windows 2000 Operating System	57
Optical Signal Regeneration	729	<i>Dario Forte</i>	
<i>Mingshan Zhao</i>		Linux Operating System	78
Optical Sources	745	<i>Mark Shacklette</i>	
<i>Tin Win and Serge Demidenko</i>		Metropolitan Area Networks	91
Lambda and Sub-Lambda Switching	767	<i>Richard J. Nieporent</i>	
<i>Mario Baldi and Yoram Ofek</i>		Terrestrial Wide Area Networks	116
Optical Cross Connects	783	<i>Gurdeep Singh Hura</i>	
<i>Wen-De Zhong</i>		Packet Switching	136
Optical Memories	795	<i>Qinqing Zhang and Qi Bi</i>	
<i>Paul W. Nutter</i>		Circuit Switching	146
Characterization of Optical Fibers	815	<i>Farid Farahmand and Qiong (Jo) Zhang</i>	
<i>Liang Chen, John Cameron, and Xiaoyi Bao</i>			
Optical Couplers and Splitters	828		
<i>Kais Dridi, Mustapha Razzak, and Habib Hamam</i>			

Message Switching	159	Voice Over Internet Protocol	468
<i>Farid Farahmand</i>		<i>Sherali Zeadally and Farhan Siddiqui</i>	
Frame Relay	172	Signaling Approaches	488
<i>Eddie Rabinovitch</i>		<i>Edmundo Monteiro, Fernando Boavida, Marilia Curado, and Luís Cordeiro</i>	
Asynchronous Transfer Mode (ATM)	183	Voice over MPLS and VoIP over MPLS	509
<i>Arjan Durresi and Raj Jain</i>		<i>Junaid Ahmed Zubairi</i>	
Broadband Integrated Services Digital Network	200	Telephone Number Mapping (ENUM)	519
<i>B. Muthukumar</i>		<i>Leslie L. Daigle</i>	
DSL (Digital Subscriber Line)	210	Web Hosting	532
<i>Milos Milosevic</i>		<i>Thomas C. Bressoud</i>	
Cable Modems	221	End-System QoS	545
<i>Shaheed N. Mohammed</i>		<i>Tarek F. Abdelzhaer and Chengdu Huang</i>	
Home Networking	230	Web Services	559
<i>Sherali Zeadally</i>		<i>Mei-Ling L. Liu</i>	
Multimedia Networking	246		
<i>Hans-Peter Dommel</i>			

Part 2: The Internet, Global Networks, and VoIP

The Internet Fundamentals	267
<i>Hossein Bidgoli</i>	
History of the Internet	280
<i>John Lucas Sherry and Nicholas David Bowman</i>	
Internet2®	294
<i>Linda Bruenjes and Carolyn Siccama</i>	
Internet Domain Name System	305
<i>Krishna Jayakar</i>	
Information Retrieval on the Internet	320
<i>Raymond F. Wisman</i>	
Internet Architecture	345
<i>Geoffrey G. Xie</i>	
TCP/IP Suite	358
<i>Prabhaker Mateti</i>	
SMTP (Simple Mail Transfer Protocol)	388
<i>Vladimir V. Riabov</i>	
IP Multicast	407
<i>Emilia Rosti</i>	
Network QoS	417
<i>Ying Lu</i>	
Internet Security Standards	428
<i>Raymond R. Panko</i>	
Technology and Standards for Low-Bit-Rate Vocoding Methods	447
<i>Miguel Arjona Ramírez and Mário Minami</i>	

Part 3: Cellular and Wireless Networks

Cellular Communications Channels	579
<i>Aarne Mämmelä and Risto Wichman</i>	
Cellular Telephony	591
<i>Elyes Ben Ali Bdira</i>	
Mobile Radio Communications	616
<i>Chi Zhou</i>	
Evolution of Mobile Cellular Networks	630
<i>Jiang Xie and Xiaoyuan Gu</i>	
Global System for Mobile Communications	642
<i>Mohamed A. Haleem and Koduvayur P. Subbalakshmi</i>	
General Packet Radio Service	658
<i>Allen H. Levesque</i>	
Location Management in Personal Communication Systems	675
<i>Jingyuan Zhang and Ivan Stojmenovic</i>	
Mobility Management in Heterogeneous Networks	685
<i>Guangbin Fan, Xuming Lu, and Song Ci</i>	
Universal Mobile Telecommunications System	699
<i>Faouzi Zarai, Noureddine Boudriga, and Mohammad S. Obaidat</i>	
International Mobile Telecommunications-2000 and 3G Wireless Systems	716
<i>Mustafa M. Matalgah and Omar M. Hammouri</i>	
Code Division Multiple Access (CDMA)	751
<i>Frank H.P. Fitzek and Marcos Katz</i>	

Time-Division Multiple Access	769	Data Monitoring and Gathering in Sensor Networks	1113
<i>Tom S. Chan</i>		<i>Symeon Papavassiliou, Stella Kafetzoglou, and Jin Zhu</i>	
Carrier Sense Multiple Access Protocols	779	In-Network Data Aggregation in Wireless Sensor Networks	1131
<i>Wei Ye</i>		<i>Kemal Akkaya and Ismail Ari</i>	
Bluetooth Technology	790	Cognitive and Software Defined Radios for Dynamic Spectrum Access	1147
<i>Brent A. Miller</i>		<i>Troy Weingart and Douglas C. Sicker</i>	
Satellite Communications Basics	802	Localization in Wireless Networks	1158
<i>Michele Luglio and Antonio Saitto</i>		<i>Slim Rekhis, Noureddine Boudriga, and Mohammad S. Obaidat</i>	
Land-Mobile Satellite Channel	815	Interference Management in Wireless Networks	1178
<i>Emilio Matricciani</i>		<i>Keivan Navaie and Shahrokh Valaee</i>	
Geosynchronous Fixed Satellite Communications	836	Wireless Wide Area Networks	1191
<i>Michele Luglio and Antonio Saitto</i>		<i>Anthony H. Smith and Raymond A. Hansen</i>	
Satellites in IP Networks	860	Wireless Broadband Access	1200
<i>Fatih Alagöz and Abbas Jamalipour</i>		<i>Hsiao-Hwa Chen and Mohsen Guizani</i>	
Global Navigation Satellite Systems	877	Indoor Wireless Infrared Communications	1223
<i>Omar Al-Bayari and Balqies Sadoun</i>		<i>Z. Ghassemlooy</i>	
Wireless LANs	896		
<i>Mohammad S. Obaidat, G. I. Papadimitriou, and S. Obaidat</i>			
Wireless LAN Standards	917		
<i>Prashant Krishnamurthy</i>			
Bit-Interleaved Coded Modulation	935		
<i>Yuheng Huang and James A. Ritcey</i>			
The Wireless Application Protocol	955		
<i>Lillian N. Cassel and Arun Srinivasa Murthy</i>			
Wireless ATM	972		
<i>Amel Meddeb and Noureddine Boudriga</i>			
Wireless IP Telephony	991		
<i>Manish Marwah and Shivakant Mishra</i>			
Wireless Internet	1000		
<i>Abbas Jamalipour</i>			
Internetworking of Heterogeneous Wireless Networks	1018		
<i>Sherali Zeadally and Farhan Siddiqui</i>			
Principles and Applications of Ad Hoc and Sensor Networks	1040		
<i>Marco Conti</i>			
Medium Access in Ad Hoc and Sensor Networks	1057		
<i>Vojislav B. Mišić and Jelena Mišić</i>			
Emerging Trends in Routing Protocols in Mobile Wireless Ad Hoc and Sensor Networks	1084		
<i>Jamal N. Al-Karaki</i>			
Broadcasting in Ad Hoc and Sensor Networks	1101		
<i>François Ingelrest, David Simplot-Ryl, Hong Guo, and Ivan Stojmenović</i>			
		Volume III: Distributed Networks, Network Planning, Control, Management, and New Trends and Applications	
		Part 1: Distributed Networks	
		Client/Server Computing Basics	3
		<i>Daniel McFarland and Darren B. Nicholson</i>	
		Groupware	16
		<i>Robert Slagter</i>	
		Network Middleware	33
		<i>Linda Volonino and Pragati Dalal</i>	
		Grid Computing Fundamentals	45
		<i>Mark Baker</i>	
		Grid Computing Implementation	63
		<i>Barry Wilkinson and Clayton Ferner</i>	
		Cluster Computing Fundamentals	79
		<i>Hong Ong and Mark Baker</i>	
		Next-Generation Cluster Networks	93
		<i>Keren Bergman, Benjamin A. Small, and Larry A. Bergman</i>	
		Utility Computing on Global Grids	110
		<i>Chee Shin Yeo, Rajkumar Buyya, Marcos Dias de Assunção, Jia Yu, Anthony Sulistio, Srikumar Venugopal, and Martin Placek</i>	

Peer-to-Peer Network Architecture	131	Computer Viruses and Worms	440
<i>Jing Wu and Michel Savoie</i>		<i>Robert Slade</i>	
Peer-to-Peer Network Applications	152	Denial of Service Attacks	454
<i>Stan Kurkovsky</i>		<i>Qijun Gu and Peng Liu</i>	
Incentive Issues in Peer-to-Peer Systems	168	E-Mail Threats and Vulnerabilities	469
<i>Yu-Kwong Kwok</i>		<i>David Harley</i>	
Storage Area Network Fundamentals	189	Virtual Private Networks	488
<i>Vladimir V. Riabov</i>		<i>G. I. Papadimitriou, M. S. Obaidat, C. Papazoglou, and A.S.Pomportsis</i>	
Fiber Channel	205	Cryptography	505
<i>Jiying Zhao</i>		<i>Ari Juels</i>	
Storage Area Networks: Architectures and Protocols	217	Access Control	518
<i>Nirwan Ansari and Si Yin</i>		<i>Sabrina De Capitani di Vimercati, Sara Foresti, Stefano Paraboschi, and Pierangela Samarati</i>	
Distributed Intelligent Networks	235	Biometrics	539
<i>G. N. Prezerakos and I. S. Venieris</i>		<i>James L. Wayman</i>	
Smart Cards: Communication Protocols and Applications	251	Firewalls	553
<i>Michael Tunstall, Konstantinos Markantonakis, Damien Sauveron, and Keith Mayes</i>		<i>James E. Goldman</i>	
Fault-Tolerant Systems	269	Authentication	570
<i>Amiya Nayak</i>		<i>Patrick McDaniel</i>	
Distributed Algorithms	286	Password Authentication	581
<i>Valmir C. Barbosa</i>		<i>Jeremy L. Rasmussen</i>	
Distributed Databases	298	Physical Security Threats and Measures	596
<i>David Coquil and Harald Kosch</i>		<i>Mark Michael</i>	
Part 2: Network Planning, Control, and Management		Computer Security Incident Response Teams (CSIRTs)	632
Network Capacity Planning	315	<i>Raymond R. Panko</i>	
<i>Priscilla Oppenheimer</i>		Backup and Recovery System Requirements	639
Network Traffic Modeling	326	<i>David R. Reavis</i>	
<i>Thomas M. Chen</i>		Business Requirements of Backup Systems	650
Network Traffic Management	340	<i>Markus Klemen, Thomas Neubauer, and Edgar R. Weippl</i>	
<i>Thomas M. Chen</i>		Evaluating Storage Media Requirements	662
Network Security Risk Assessment and Management	354	<i>David R. Reavis</i>	
<i>Dan Port, Rick Kazman, and David Klappholz</i>		Business Continuity Planning	671
Network Reliability and Fault Tolerance	372	<i>Marco Cremonini and Pierangela Samarati</i>	
<i>Matthew Liotine</i>		E-Mail and Internet Use Policies	689
Social Engineering	384	<i>Nancy J. King</i>	
<i>Benjamin Böck, Markus D. Klemen, and Edgar R. Weippl</i>		Computer Network Management	714
Intrusion-Detection Systems	403	<i>Jian Ren</i>	
<i>Peng Ning and Sushil Jajodia</i>		Part 3: Computer Network Popular Applications and Future Directions	
Network Attacks	421	E-mail and Instant Messaging	733
<i>Mohamed Hamdi and Noureddine Boudriga</i>		<i>Bhagyavati</i>	

Application Service Providers (ASPs) <i>Bandula Jayatilaka</i>	742	Mobile Commerce <i>Vijay Atluri</i>	915
Videoconferencing <i>Ketan Mayer-Patel</i>	755	Online News <i>Bruce Garrison and Marcus Messner</i>	927
Computer Conferencing: Protocols and Applications <i>William R. Gillis and Colleen Taugher</i>	768	Travel and Tourism <i>Ulrike Gretzel, Youcheng Wang, and Daniel R. Fesenmaier</i>	943
Telecommuting and Telework <i>Michael Workman</i>	777	Web-Based Training <i>Patrick J. Fahy</i>	962
Online Banking <i>Ronnie J. Phillips</i>	791	RFID (Radio-Frequency Identification) <i>Stephen A. Weis</i>	974
Digital Libraries <i>Cavan McCarthy</i>	801	Active Networking <i>Stephen F. Bush</i>	985
Computer Conferencing and Distance Learning <i>Liam Rourke and Heather Kanuka</i>	831	Applications of Biological Concepts to Designs of Computer Networks and Network Applications <i>Tatsuya Suda, Tadashi Nakano, and Keita Fujii</i>	1012
Electronic Commerce <i>Charles Steinfield</i>	843	Nanotechnology for Communication Systems <i>Syed H. Murshid and Azhar M. Khayrattee</i>	1022
Electronic Data Interchange (EDI) <i>Matthew K. McGowan</i>	860	Molecular Communication: New Paradigm for Communication among Nanoscale Biological Machines <i>Michael Moore, Akihiro Enomoto, Tatsuya Suda, Tadashi Nakano, and Yutaka Okaie</i>	1034

Preface

The Handbook of Computer Networks is the first comprehensive examination of the core topics in the computer network field. *The Handbook of Computer Networks*, a 3-volume reference work, with 202 chapters, 3400+ pages, is a comprehensive coverage of the computer network field with coverage of the core topics.

The primary audience is the libraries of 2-year and 4-year colleges and universities with Computer Science, Computer Engineering, Network Engineering, Telecommunications, Data Communications, MIS, CIS, IT, IS, Data Processing, and Business departments, public and private libraries and corporate libraries throughout the world, and educators and practitioners in the networking and telecommunications fields.

The secondary audience is a variety of professionals and a diverse group of academic and professional courses for the individual volumes.

Among industries expected to become increasingly dependent upon the computer networks and telecommunications and active in understanding the many issues surrounding this important and fast-growing field are: government agencies, military, education, libraries, health, medical, law enforcement, accounting firms, law firms, justice, manufacturing, financial services, insurance, communications, transportation, aerospace, energy, biotechnology, retail, and utilities.

Each volume incorporates state-of-the-art core information and computer networks and telecommunications topics, practical applications, and coverage of the emerging issues in the computer networks field.

This definitive 3-volume *Handbook* offers coverage of both established and cutting-edge theories and developments in the computer networks and telecommunications fields. The *Handbook* contains chapters from global experts in academia and industry. The *Handbook* offers the following unique features:

1. Each chapter follows a unique format including Title and Author, Outline, Introduction, Body, Conclusion, Glossary, Cross-References, and References. This unique format assists the readers to pick and choose various sections of a chapter. It also creates consistency throughout the entire series.
2. The *Handbook* has been written by more than 270 experts and reviewed by more than 1000 academics and practitioners chosen from around the world. These diverse collections of expertise have created the most definitive coverage of established and cutting-edge theories and applications of this fast-growing field.
3. Each chapter has been rigorously peer reviewed. This review process assures the accuracy and completeness of each topic.
4. Each chapter provides extensive online and off-line references for additional reading. This will enable the readers to go further with their understanding of a given topic.
5. More than 1000 illustrations and tables throughout the series highlight complex topics and assist further understanding.
6. Each chapter provides extensive cross-references. This helps the readers to read other chapters related to a particular topic, providing a one-stop knowledge base for a given topic.
7. More than 2500 glossary items define new terms and buzzwords throughout the series, assisting in understanding of concepts and applications.
8. The *Handbook* includes a complete table of contents and index sections for easy access to various parts of the series.
9. The series emphasizes both technical as well as managerial issues. This approach provides researchers, educators, students, and practitioners with a balanced understanding and the necessary background to deal with problems related to understanding computer networks and telecommunications issues and to be able to design a sound computer and telecommunications system.
10. The series has been developed based on the current core course materials in several leading universities around the world and current practices in leading computer, telecommunications, and networking corporations. This format should appeal to a diverse group of educators and researchers in the networking and telecommunications fields.

We chose to concentrate on fields and supporting technologies that have widespread applications in academic and business worlds. To develop this *Handbook*, we carefully reviewed current academic research in the networking field in leading universities and research institutions around the world.

Computer networks and telecommunications, network security, management information systems, network design and management, computer information systems (CIS), and electronic commerce curriculums, recommended by the Association of Information Technology Professionals (AITP) and the Association for Computing Management (ACM) were carefully investigated. We also researched the current practices in the networking field carried out by leading networking and telecommunications corporations. Our work assisted us in defining the boundaries and contents of this project. Its chapters address technical as well as managerial issues in the networking and telecommunications fields.

TOPIC CATEGORIES

Based on our research, we identified nine major topic areas for the Handbook:

- Key Concepts
- Hardware, Media, and Data Transmission
- Digital and Optical Networks
- LANs, MANs, and WANs
- The Internet, Global Networks, and VoIP
- Cellular and Wireless Networks
- Distributed Networks
- Network Planning, Control, and Management
- Computer Network Popular Applications and Future Directions

Although these nine categories are interrelated, each addresses one major dimension of the computer networks and telecommunications fields. The chapters in each category are also interrelated and complementary, enabling readers to compare, contrast, and draw conclusions that might not otherwise be possible.

Though the entries have been arranged logically, the light they shed knows no bounds. The *Handbook* provides unmatched coverage of fundamental topics and issues for successful design and implementation of a computer network and telecommunications systems. Its chapters can serve as material for a wide spectrum of courses such as:

- Grid Computing
- Distributed Intelligent Networks
- Multimedia Networking
- Peer-to-Peer Networks
- Cluster Computing
- Voice over IP
- Storage Area Networks
- Network Backup and Recovery Systems
- Digital Networks
- Optical Networks
- Cellular Networks
- Wireless Networks
- Telecommunications Systems
- Computer Network Management

Successful design and implementation of a sound computer network and telecommunications systems requires a thorough knowledge of several technologies, theories, and supporting disciplines. Networking researchers and practitioners have had to consult many resources to find answers. Some of these sources concentrate on technologies and infrastructures, some on applications and implementation issues, and some on managerial concerns. This *Handbook* provides all of this relevant information in a comprehensive three-volume set with a lively format.

Each volume incorporates core networking and telecommunications topics, practical applications, and coverage of the emerging issues in the networking and telecommunications fields. Written by scholars and practitioners from around the world, the chapters fall into nine major subject areas:

Key Concepts

Chapters in this group examine a broad range of topics. Fundamental theories, concepts, technologies, and applications related to computer networks, data communications, and telecommunications are discussed. These chapters explain the OSI reference model and then discuss various types of compression techniques including data, image, video, speech, and audio compression. This part concludes with a discussion of multimedia streaming and high definition television (HDTV) as their applications are on the rise. The chapters in this part provide a solid foundation for the rest of the Handbook.

Hardware, Media, and Data Transmission

Chapters in this group concentrate on the important types of hardware used in network and telecommunications environments and then examine popular media used in data communications including wired and wireless media. The chapters in this part explain different types of modulation techniques for both digital and optical networks and conclude with coverage of various types of multiplexing techniques that are being used to improve the efficiency and effectiveness of communications media.

Digital and Optical Networks

Chapters in this group discuss important digital and optical technologies that are being used in modern communication and computer networks. Different optical switching techniques, optical devices, optical memories, SONET, and SDH networks are explained.

LANs, MANs, and WANs

This group of chapters examines major types of computer networks including local, metropolitan, and wide area networks. Popular types of operating systems used in a LAN environment are discussed, including Windows and Linux. The chapters also examine various types of switching techniques including packet, circuit, and message switching. The chapters discuss broadband network applications and technologies and conclude with a discussion of multimedia networking.

The Internet, Global Networks, and VoIP

Chapters in this group explore a broad range of topics. They review the Internet fundamentals, history, domain name systems, and Internet2. The architecture and functions of the Internet and important protocols including TCP/IP, SMTP, and IP multicast are discussed. The chapters in this group also explain the network and end-system quality of service and then discuss VoIP and its various components, protocols, and applications.

Cellular and Wireless Networks

Chapters in this group explain cellular and wireless networks. Major standards, protocols, and applications in the cellular environment are discussed. This includes a detailed coverage of GSM, GPRS, UMTS, CDMA, and TDMA. The chapters in this group explore satellite communications

principles, technologies, protocols, and applications in detail. The chapters conclude with coverage of wireless wide area networks and wireless broadband access.

Distributed Networks

The chapters in this group investigate distributed networks, their fundamentals, architectures, and applications. Grid computing, cluster computing, and peer-to-peer networks are discussed in detail. These chapters also explore storage area networks, fiber channels, and fault tolerant systems. This part concludes with a discussion of distributed algorithms and distributed databases.

Network Planning, Control, and Management

The chapters in this group discuss theories, methodologies, and technologies that enhance successful network planning, control, and management. After discussion of network capacity planning and network modeling, the chapters concentrate on the identification of threats and vulnerabilities in a network environment. The chapters then present a number of tools and technologies that if properly utilized could significantly improve the integrity of data resources and computer networks by keeping hackers and crackers at bay. This part concludes with a discussion of business continuity planning, e-mail, and Internet use policies, and computer network management.

Computer Network Popular Applications and Future Directions

Chapters in this group present several popular applications of computer networks and telecommunications systems. These applications could not have been successfully utilized without a sound computer network and telecommunications system. Some of these applications include conferencing, banking, electronic commerce, travel and tourism, and Web-based training and education. This part concludes with a discussion of future trends in computer networking including biologically inspired networking, active networks, and molecular communication.

Specialists have written the *Handbook* for experienced and not so experienced readers. It is to these contributors that I am especially grateful. This remarkable collection of scholars and practitioners have distilled their knowledge

into a fascinating and enlightening one-stop knowledge base in computer networks and telecommunications that “talks” to readers. This has been a massive effort, but one of the most rewarding experiences I have ever had. So many people have played a role that it is difficult to know where to begin.

I should like to thank the members of the editorial board for participating in the project and for their expert advice on help with the selection of topics, recommendations for authors, and reviewing the materials. Many thanks to more than 1000 reviewers who devoted their time by providing advice to me and the authors for improving the coverage, accuracy, and comprehensiveness of these materials.

I thank my senior editor Matt Holt, who initiated the idea of the *Handbook*. Through a dozen drafts and many reviews, the project got off the ground and then was managed flawlessly by Matt and his professional team. Matt and his team made many recommendations for keeping the project focused and maintaining its lively coverage.

Jessica Campilango, our editorial coordinator, assisted our authors and me during the many phases of its development. I am grateful for all her support. When it came to the production phase, the superb Wiley production team took over. Particularly I want to thank Deborah Schindlar and Miriam Palmer-Sherman, our production editors. I am grateful for all their hard work. I also want to thank Lynn Lustberg, our project manager from ICC Macmillan Inc. Her thoroughness made it easier to complete the project. I am grateful to all her efforts. I thank Kim Dayman and Christine Kim, our marketing team, for their impressive marketing campaign launched on behalf of the *Handbook*.

Last, but not least, I want to thank my wonderful wife, Nooshin, and my two children, Mohsen and Morvareed, for being so patient during this venture. They provided a pleasant environment that expedited the completion of this project. Mohsen and Morvareed assisted me in sending out thousands of e-mail messages to our authors and reviewers. Nooshin was a great help in designing and maintaining the authors’ and reviewers’ databases. Their efforts are greatly appreciated. Also, my two sisters, Azam and Akram, provided moral support throughout my life. To this family, any expression of thanks is insufficient.

Hossein Bidgoli
California State University, Bakersfield

Guide to The Handbook of Computer Networks

The Handbook of Computer Networks is a comprehensive coverage of the relatively new and very important field of computer networks and telecommunications systems. This reference work consists of three separate volumes and 202 different chapters on various aspects of this field. Each chapter in the Handbook provides a comprehensive overview of the selected topic, intended to inform a broad spectrum of readers, ranging from computer network professionals and academicians to students to the general business community.

In order that you, the reader, will derive the greatest possible benefit from *The Handbook of Computer Networks*, we have provided this Guide. It explains how the information within it can be located.

Organization

The Handbook of Computer Networks is organized to provide the maximum ease of use for its readers. All of the chapters are arranged logically in these three volumes. Individual volumes could be used independently. However, the greatest benefit is derived if all three volumes are investigated.

Table of Contents

A complete table of contents of the entire Handbook appears at the front of each volume. This list of chapter titles represents topics that have been carefully selected by the editor-in-chief, Dr. Hossein Bidgoli, and his colleagues on the Editorial Board.

Index

A Subject Index for each individual volume is located at the end of each volume. This index is the most convenient way to locate a desired topic within the Handbook. The subjects in the index are listed alphabetically and indicate the page number where information on this topic can be found.

Chapters

The author's name and affiliation are displayed at the beginning of the chapter. All chapters in the Handbook are organized according to a standard format as follow:

Title and Author

Outline

Introduction

Body

Conclusion

Glossary

Cross References

References

Outline

Each chapter begins with an outline indicating the content of the chapter to come. This outline provides a brief overview of the chapter, so that the reader can get a sense of what is contained there without having to leaf through the pages. It also serves to highlight important subtopics that will be discussed within the chapter. For example, the chapter "The Internet Fundamentals" includes sections for Information Superhighway and the World Wide Web, Domain Name Systems, Navigational Tools, Search Engines, and Directories.

The Outline is intended as an overview and thus it lists only the major headings of the chapter. In addition, second-level and third-level headings will be found within the chapter.

Introduction

The text of each chapter begins with an introductory section that defines the topic under discussion and summarizes the content of the chapter. By reading this section the readers get a general idea regarding a specific chapter.

Body

The body of each chapter discusses the items that were listed in the outline section of each chapter.

Conclusion

The conclusion section provides a summary of the materials discussed in a particular chapter. This section leaves the readers with the most important issues and concepts discussed in a particular chapter.

Glossary

The glossary contains terms that are important to an understanding of the chapter and that may be unfamiliar to the reader. Each term is defined in the context of the particular chapter in which it is used. Thus, the same term may be defined in two or more chapters with the detail of the definition varying slightly from one chapter to another. The Handbook includes approximately 2700 glossary terms. For example, the chapter "The Internet Fundamentals" includes the following glossary entries:

Extranet A secure network that uses the Internet and Web technology to connect two or more intranets of trusted business partners, enabling business-to-business, business-to-consumer, consumer-to-consumer, and consumer-to-business communications.

Intranet A network within the organization that uses Web technologies (TCP/IP, HTTP, FTP, SMTP, HTML, XML, and its variations) for collecting, storing, and disseminating useful information throughout the organization.

Cross References

All the chapters in the Handbook have cross references to other chapters. These appear at the end of the chapter, following the chapter text and preceding the References. The cross references indicate related chapters that can be consulted for further information on the same topic. The Handbook contains more than 2000 cross references in all. For example, the chapter “The Internet Fundamentals” has the following cross references:

Electronic Commerce, Electronic Data Interchange (EDI), Electronic Payment Systems, History of the Internet, Internet2, Internet Domain Name System, Information Retrieval on the Internet.

References

The References appears as the last element in a chapter. It lists recent secondary sources to aid the reader in locating more detailed or technical information. Review articles and research papers that are important to an understanding of the topic are also listed. The References in this Handbook are for the benefit of the reader, to provide references for further research on the given topic. Thus, they typically consist of a dozen to two dozen entries. They are not intended to represent a complete listing of all materials consulted by the author in preparing the chapter.

INTRODUCTION TO LOCAL AREA NETWORKS

A network is a collection of two or more devices linked together. Typically the connection is a physical connection using wires or cables, although wireless connections are also possible for networks. In addition to the hardware required for this connection, there is communication software necessary to allow the communications to occur. Networks facilitate the sharing of resources including hardware, software, and data as well as providing a mechanism for enhancing communications between computers and users of computers.

Networks can be primarily classified as local area networks (LANs) and wide area networks (WANs). Traditionally the distinction between these classifications of networks has been the size or radius of the network. A LAN is a network where the computers are physically close together. This may mean that the computers are in the same room, the same building, or even at the same site. Computers in a WAN are often distributed beyond metropolitan areas. WANs are made up of multiple LANs as in the case of the Internet. Other classifications of networks may include personal area networks (PANs), metro area networks (MANs), and storage area networks (SANs). Networks can also be classified by the network protocols at the physical/data-link layers of the network. Often the distinction between LANs and WANs depends on who controls the network. WANs are typically controlled by the Internet service provider (ISP), whereas LANs are more often controlled by the local network administrator.

Why Do We Want to Network Computers?

In the early days of computing, there were a small number of computers, which could be used by only one person at a time. With the emergence of time-sharing linking terminals to mainframe computers in the 1960s, individual computers were able to be used by more than one user simultaneously. This significantly expanded the functionality of computers, but had several limitations. Chief among the limitations was that as more users connected to the shared computer, the amount of resources available for each user's transaction diminished. In the late 1970s and early 1980s, the personal computer (PC) resulted in the return of one computer—one user (Figure 1). Finally, in the 1990s, hardware and software became available to network multiple PCs (Figure 2). Before LANs, copies of data needed to be kept by every user of the data on each computer and copies of software or application programs used by each user had to be installed on each computer. Printing a document required that every computer needed its own printer or the user walked to the computer with the attached printer and loaded the document on that computer. Networking computers alleviates some of this need for redundancy, although there will still be some redundancy needed for backup purposes.

Figure 1: Before networks

Figure 2: Networked computers

Data in a networked environment can be shared. Each user can access the data from other computers via the network. This feature of networks helped speed the transition from mainframe computing to networked computing. Networked computers allow important information to be shared among different computer users. Rather than keeping copies of data on each computer, one copy of the data is kept on a server and accessed remotely via the network. Changes to the data are made once, and then accessed by all.

Rather than installing software on every computer, software can be shared in a network environment. Application programs can be stored on one computer and run remotely from another computer. In an office configured with multiple non-networked computers, each computer must have installed a copy of each application program that is used. In addition to the need to purchase copies of the software for each computer, the software must be installed and maintained on each computer. Network versions of many application programs can be purchased. A networked version of software is typically much cheaper than purchasing large numbers of a particular piece of software. Network software only needs to be installed once on a server allowing users on the other computers to access the software. When it is time to upgrade the software, it only needs to be done once on the server, instead of on all of the computers. Installing software on multiple computers simultaneously can be facilitated using networked computers with the software residing on the server.

Networks facilitate the sharing of hardware. Hardware can be installed in one location and accessed over the network from other computers. Printers and scanners can be networked so that multiple users can share the same printer or other hardware device. Other peripheral devices might include CD-ROMs, DVD-ROMs, and other shared devices.

Before LANs, computer users that needed to communicate with others had to use traditional methods such as a physical visit to another user, a telephone call, or a letter delivered to the other person. Communications have been enhanced tremendously with e-mail and instant messaging (IM) facilitated by the use of LANs.

TYPES OF LANs

Computers that can access a network are often referred to as networked workstations or hosts. Any device (workstation, printer, modem) that connects to a network is called a node.

Many of the networks in the early 1980s only allowed the sharing of resources directly between PCs. These types of networks are called peer-to-peer networks. Each

computer has the same potential for sharing files and hardware devices. A peer-to-peer network is easy to design and maintain, but is limited in its capabilities and in capacity.

Most networks today are classified as client/server networks. In a client/server network, one or more of the computers function as servers, whereas the remainder of the computers function as clients. A server is a computer that provides a service, whereas a client computer makes use of the service provided. Examples of servers include print servers, file servers, mail servers, and Web servers. A print server (Figure 3) is a computer or peripheral device that provides access to one or more printers across the network. Print servers were among the earliest type of servers. A file server provides a repository for files that can be accessed by other computers over the network. Mail or communication servers manage the flow of incoming and outgoing electronic mail for users accessing the server from client workstations. Web servers are computers running software that provides access to World Wide Web documents.

Computers on a network can run more than one type of server software and can function as multiple types of servers. For example, a computer can have both Web server and e-mail server software installed and function as both a Web server and a communications server. A workstation can function both as a server and simultaneously as a client for another server. For example, a computer can be a Web server running Web server software, but print through the network using another computer that functions as a print server. It is generally not recommended that one computer function as more than one server. Doing so increases the likelihood of one point of attack on the network. However, using a separate computer for each server results in more potentially vulnerable computers and increased administration costs. This increases the points of attack and needs to be taken into consideration. Running only one main service (e.g., e-mail) can significantly increase the reliability of the network, because instability and maintenance associated with that service will typically not affect other services running on separate servers.

Similarly, it is recommended that servers not function as clients. Using a server as a client increases the

Figure 3: Print server

opportunity for introducing security vulnerabilities that might compromise the security of the server.

Difference Between LANs and WANs

As mentioned earlier, one distinction between LANs and WANs is the radius of the network. A LAN is a network where the nodes are physically close together. Typically, the nodes are in the same room, but they can be in the same building or in nearby buildings. In today's networks, the nodes are often scattered across the organization. Historically, networks with a radius greater than a kilometer or two are typically classified as WANs. Other ways of distinguishing between LANs and WANs include transmission speed and ownership. LANs are typically faster networks with speeds of at least 10 Mbps to 10 Gbps. WANs are generally significantly slower, with most WANs operating at speeds around 1.54 Mbps (T1/DS1) or 45 Mbps (T3/DS3). Today very high-speed WANs exist that approach LAN speeds. LANs are owned by the organization where the network is used. WANs generally use hardware that is owned and operated by a network provider, although there are public agencies that do own and operate their own WANs. A final distinction is with the difference in technologies used by LANs and WANs. The next section describes two of the technologies (Ethernet and token ring) used by LANs. WANs typically use different technologies, including Frame Relay, ATM, and X.25. Recently, Ethernet has started to be deployed in WANs as Metro Ethernet. These distinctions have continued to blur significantly over the last several years as WANs get faster and LANs get larger.

LAN Topology

LANs can be organized in a variety of ways. One way to classify networks is by their electrical configuration or logical topology. This is often called the signal topology and is determined by how the nodes communicate with each other. This is basically the way the data is transmitted between nodes. The two main logical topologies are bus and ring.

In a traditional bus network, the data is broadcast from one node to all other nodes in the LAN even though the data may be intended for only one node. Each of the nodes receives the data, but it is only "read" by the node where the data is intended. The data includes an address for the destination node or nodes. Ethernet is the primary technology that supports the bus logical topology.

In a ring network, the data is sent from one node to the next in sequential order in a circular fashion. Each node inspects the destination address of the data packet to determine if the data is meant for it. If the data is not meant for the node, the data packet is passed along to the next node in the logical ring.

LANs can also be classified by the physical layout of the network. The way that the nodes are physically connected to the network is known as the physical topology. The physical topology of the network can have a significant influence on a LAN's performance and reliability. The three main physical topologies are bus, ring, and star. There are also hybrid networks including star-bus and star-ring, which incorporate parts of both types of

networks. These "mixed" topologies are more common implementations.

In a bus topology (Figure 4), the nodes are arranged in a linear fashion, with terminators (Figure 5) on each end. The nodes are connected to the "bus" with connectors. Bus networks are easy to install but not very reliable. Any break in the connection, or a loose connection, will bring down a portion of the network and possibly the entire network. This is old technology rarely used in modern LANs.

In a ring topology (Figure 6), each connected node is an active participant in the ring network. Each data packet is received by a node, and, if it is not intended for the node, it is passed along the ring to the next node. If one of the nodes or its network card malfunctions, the network stops functioning.

In a star network (Figure 7) each connected node is attached to a central device. Typically this device is a hub or a switched hub, but it could also be other devices, including a multistation access unit. Star networks are more economical and easier to troubleshoot. Star networks do require an additional hardware device like a hub or switch, and additional cable. Because each node is independently connected to the central device, a failure

Figure 4: Bus network

Figure 5: Terminator and BNC T-connector

Figure 6: Ring network

Figure 7: Star physical network

only affects the single node. Of course if the central device fails, the entire network fails.

A network's physical and logical topologies are not necessarily the same. For example, a twisted-pair Ethernet network using a hub is physically arranged with a star topology, although the data is transmitted via a bus topology.

LAN Architecture

The most dominant network architecture for LANs today is Ethernet. Ethernet was developed by Robert Metcalfe and others at the Palo Alto Research Center (PARC) in the mid-1970s (Metcalfe and Boggs, 1976).

Ethernet uses the carrier sense multiple access with collision detection (CSMA/CD) access method. Carrier sense refers to each node being able to "listen" for other users using the network, only attempting to use the network if it is not being used. Multiple access means that any node on the network may use the network without requiring further permission. Collision detection lets the node know if a message was not delivered and controls the mechanism for retransmitting the data packet. CSMA/CD is most efficient when there are a limited number of nodes requesting access to the network. As the radius of the network and number of nodes on the network increases, the likelihood of collisions increases.

In 1981, the first Ethernet standard was developed by a consortium comprised of Digital, Intel, and Xerox. This was followed by a second Ethernet standard in 1982, called Ethernet II. Ethernet II (Figure 8) had the following characteristics:

- bus topology
- coaxial cable using baseband signaling
- 10 Mbit/sec data rate
- maximum station separation of 2.8 kilometers
- 1024 maximum number of stations

In addition, the Institute of Electrical and Electronics Engineers (IEEE) developed a standard, also often referred to as Ethernet, called the IEEE 802.3 standard (Figure 9). The two standards are very similar and have similar frame layouts as shown. Although Ethernet has continued to evolve over the past 25 years, the main concepts have remained.

Ethernet can run over a variety of media types including several types of coax cable, twisted pair cable, and fiber optic cable, as well as wireless formats, including radio signals and infrared. Table 1 lists several of these media types. The first number indicates the speed in megabits, the "base" refers to baseband transmission meaning that the entire bandwidth is dedicated to just one data channel, and the last number or letter indicates the approximate maximum segment length or the media type.

A second network architecture, Token Ring or IEEE 802.5 (Figure 10), was developed in early 1970s by IBM. A Token Ring network is often preferred for time-sensitive and mission-critical applications. Token Ring networks use the token passing access method. Only the computer that has the 24-bit packet of data called the token may use the network. This token is generated by a designated computer called the active monitor and passed around the ring until one of the computers wishes to use the network. When a computer wants to use the network, it seizes the token, changes the status of the token to busy, inserts its data frame onto the network, and only releases the token when it receives a confirmation that the data packet has been received. A Token Ring network uses a sequential

Figure 10: IEEE 802.5 token frame layout

logical topology, which was traditionally a ring physical topology but now is typically a star topology. IBM specified two architectures that operated at 4 and 16 Mbps. Token Ring networks are no longer widely supported. Ethernet and Token Ring standards are typically associated with the data-link layer of the Open Systems Interconnection Basic Reference (OSI) Model, in particular the Media Access Control (MAC) sub-layer that defines the access method and framing format corresponding to the LAN protocol.

In the mid-1980s, the American National Standards Institute (ANSI) X3T9.5 standards committee released a standard for data communications in a local area network called Fiber Distributed Data Interface (FDDI). FDDI is similar to token ring, using dual counter-rotating rings. The primary ring is used for data transmission with the main function of the secondary ring for backup. FDDI can extend the range of a local area network up to 100 kilometers at 100 Mbps. FDDI uses optical fiber as the transmission media. A similar architecture uses copper and is called Copper Distributed Data Interface (CDDI).

LAN HARDWARE AND MEDIA

There are a variety of media choices for connecting computers to a local area network. Early networks used copper wires—either coaxial or twisted pair. The standards detailing the LAN hardware and media are associated with the physical layer of the OSI Model.

Copper Wire

Coaxial cable consists of a center wire surrounded by insulation and then a grounded shield of braided wire. The shield minimizes electrical and radio frequency interference. A coaxial cable was typically referred to as either thinnet or thicknet. Thicknet (Figure 11) was the original standard for Ethernet and is defined by the IEEE 10Base-5 standard and uses 50 ohm coaxial cable (RG-8 or RG-11 A/U) with maximum lengths of 500 meters. Thinnet (Figure 12) is defined by the IEEE 10Base-2 standard and uses 50 ohm coaxial cable (RG-58 A/U) with maximum lengths of 185 meters. RG-58 is similar to the coaxial cable

Figure 11: RG-58 coaxial cable

Figure 12: RG-8 coaxial cable

Figure 13: BNC connector

Figure 14: CAT5 patch cable

Figure 15: CAT6 twisted pairs of wires

used with cable TVs. Cables in the 10Base-2 system connect to other devices with BNC connectors (Figure 13).

Twisted pair networking cable also has two different forms—UTP (unshielded twisted-pair) and STP (shielded twisted-pair). Both types of cable consist of either two or four pairs of wire. Each pair is twisted together. Shielded twisted-pair cable has an additional layer of conducting material surrounding the twisted-pairs of wires. Unshielded twisted-pair cable does not have the additional layer. Telephone companies use UTP cable with two twisted-pairs of wires. UTP is the most common and least expensive method for networking computers (Figure 14). There are seven categories of unshielded twisted-pair cabling ranging from Category 1 (CAT1), which is ordinary telephone cable used to carry voice, to Category 7 (CAT7) (Figure 15), which is designed for high-speed networks. CAT6 and CAT7 use 23 AWG copper as opposed to the 24 AWG used in CAT5/CAT5e and lower, therefore the signal attenuates (loses signal strength) less with speed and

distance. CAT6 also uses a tighter twist ratio that cuts down on internal crosstalk. CAT7 uses individually foil-shielded twisted-pairs to minimize crosstalk. UTP and STP use RJ45 connectors (Figure 16) to plug into the different networking devices.

Fiber Wire

Fiber-optic cable (Figure 17) has become more common as demand increases for higher transmission speeds. Fiber-optic cable transmits data using pulsating laser light instead of electricity. Fiber-optic cable consists of a thin glass or plastic filament protected by thick plastic padding and an external plastic sheath. A light signal allows the data to travel faster, farther, more reliably, and more securely than electricity. Fiber cable can send reliable signals at speeds of 100 GB/s as far as 40 kilometers. Unfortunately, fiber-optic cable is expensive to buy, install, and maintain. Although not impossible, it is more difficult to intercept data carried by fiber-optic cable. Fiber-optic cable is less susceptible to “noise” and interference.

Wireless

Wireless LANs have become commonplace in businesses and homes. WLANs are often referred to as WiFi or 802.11 networks. Early wireless LANs were light-based using infrared light to transmit the data. Wireless LANs that are light-based require line of sight for all devices on the network. Because of this limitation and the slow data speed, there are only a few light-based infrared wireless LANs.

Most wireless LANs use radio waves to transmit the data. Each device in a wireless network requires an antenna to receive and transmit the radio signals. Wireless LANs can be peer-to-peer or ad-hoc networks (Figure 18), which only requires that each device be equipped with a wireless network card that contains the antenna, or a more complete network called an infrastructure network that requires an access point (Figure 19). The access point

Figure 16: RJ45 connector

Figure 17: Fiber-optic cable

Figure 18: Peer-to-peer wireless network

Figure 19: Wireless network with access point

Figure 20: Network interface card (NIC) with RJ45, BNC, and AUI connections

contains an antenna, a radio transmitter, and a wired network interface, typically an RJ45 port. The access point acts as a base station (similar to a hub) for the wireless network and also as a bridge between the wireless and wired networks.

Regardless of whether the network is wired or wireless, every device on the network must be connected to the network with a network adapter or network interface card (NIC) (Figures 20, 21, and 22). The card must be physically connected to the device, either installed directly into a slot in the computer or connected via a port like a USB port. Most laptops and tablet PCs manufactured after 2004 have both wired and wireless interfaces built-in. The network card provides the interface between the node on the network and the network media. Because communication in a wireless network occurs through the air, it is easier for the signal to be intercepted. As wireless becomes more pervasive, security has become a significant issue.

Figure 21: Network interface card with RJ45 connection

Figure 22: PCMCIA wireless NIC

Hardware Devices

Several factors limit the radius of a local area network. The farther a signal travels along the wire or through the air, the more likely it is to be degraded by noise. As the signal travels, it loses energy and becomes weaker, thus becoming difficult to read. As the network radius increases, it becomes more likely that two or more machines will transmit at the same time, causing a “collision.” It will take longer for the machines to detect the collision. There are several ways to increase the radius of a network.

The simplest device to use is a repeater. A repeater (Figure 23) is an electronic device used to extend the distance of a network by amplifying the signal and reducing the electrical interference within the network. The repeater relays the data from one segment of the network to another without inspecting or modifying the data. Repeaters can also be used to connect segments of the network that use different cable media. Repeaters operate at the physical layer of the network.

A hub (Figure 24) is a multiport repeater that allows the distance of the network to be extended as well as allowing multiple devices to connect to the LAN. A hub is a device that brings all of the connections together (Figure 25). Like a repeater, the hub does not inspect or modify the data. Ethernet networks with only hubs and repeaters are constrained by the 5-4-3 rule that limits the connections between two nodes to no more than five segments each with no more than four repeaters where no more than three of the repeaters connect additional active nodes.

Figure 23: Repeater

Figure 24: Four-port hub

Figure 25: Hub connecting two hosts

Figure 26: Bridges

Repeaters and hubs boost the signals on a network, but don't solve problems involving collisions. Other devices, however, alleviate this problem by limiting traffic on the network. A bridge (Figure 26) is an electronic device that connects two or more networks typically running the same network protocols. It allows the isolation of the different networks. The different networks may have different topologies. Bridges are used to increase the efficiency of a network by limiting the collision domain to "one side" of the bridge. By doing this, networks can be expanded without a significant increase of traffic. Bridges operate at the physical and data-link layers and make use of the physical addresses associated with the network cards. Segmenting can also improve LAN traffic by isolating workstations that pass large files or data set between them.

A switch (Figure 27) is a multiport bridge. Switches are often referred to as switching hubs. A switch combines the appearance and functionality of a hub with the

Eight-port switch

Figure 27: Switches

additional functionality of a bridge. Switches provide full duplex transmission between nodes eliminating collisions and enhancing the performance of the networks. Switches have typically replaced hubs in most local area network installations. A specialized type of bridge or switch called a "translating bridge" or gateway can be used to connect two or more networks using different protocols, for example Ethernet and token ring.

Although typically not part of a LAN, routers provide the interface between a LAN and WAN, or between different LANs. Routers route the traffic between different networks by maintaining tables of networks and their addresses. Routers forward layer 3 IP packets between different layer 2 domains. Routers are more sophisticated than switches and bridges and work at a higher level of the network.

LAN SOFTWARE

LAN software can be classified into three categories, network operating systems, network utilities, and network applications software. Not too many years ago, operating systems and network operating systems were distinct. Today almost all operating systems have the client functionality of a network operating system built in. In other words, you do not need to add any additional software to the operating system to get the computer to function on a network. All of today's popular operating systems including all recent versions of Microsoft Windows, all versions of Linux and UNIX, and all versions of the Macintosh OS support the connection of a computer to a network right out of the box. In addition to the usual computing tasks performed by an operating system, a network operating system also:

- manages the network connection
- manages data traffic between the computer and the network
- manages the flow of data between the different devices
- manages communication and messages between the network users
- provides for security of the data and other resources available on the network

The network operating system provides the interface between the LAN hardware and the applications running on the host.

Included with most of the network operating systems are specific network utilities like ping, ARP, and trace-route, which provides network control/management functions. Ping sends an Internet Control Message Protocol

(ICMP) ECHO_REQUEST packet to another device and waits for an ECHO_REPLY packet of data from the other device. This gives an indication of the time it takes to reach the target machine. Ping is a useful utility for troubleshooting networking problems. Address resolution protocol (ARP) is used to map the physical address of a networked device to the corresponding network IP address that has been assigned to the device. Traceroute uses the ping utility to map the route packets of data take from a source to a destination machine. Network operating systems typically include drivers for most network adapters so that the adapter can be plugged into the computer and the computer can be functioning on the network without too much additional configuration.

Network application software includes client front end software that is specific for use by client computers. This would include programs like Web browsers and e-mail software clients that would be run when needed. Hosts functioning as servers would have server software that would be constantly running waiting for connections from clients. Web servers and e-mail servers would be examples of this. Other types of network application software would include database client and server software as well as groupware software.

ROLE AND APPLICATIONS OF LANs

One of the major uses of LANs is to facilitate connections by users to the Internet. This requires the connection of the LAN to the Internet either via a dial-up telephone connection, a broadband connection, or a leased line. A dial-up connection requires a modem that converts the network's serial digital signal to the phone line's analog signal. A broadband connection typically requires a digital subscriber line (DSL), Integrated Services Digital Network (ISDN), or cable modem and a router and hub. Most commercial off-the-shelf devices include the functionality of a router, a hub, and often a wireless access point. A leased line connection requires a router that is then connected to another hardware device called a channel service unit/data service unit (CSU/DSU). The CSU/DSU in turn connects the network's router to the end of the leased line (e.g., T1 or T3) and converts the network's serial data signal to and from the leased line's digital signal. The leased line provides a high-speed Internet connection for the organization owning the LAN. The leased line is typically leased from a telecom provider through an ISP. The ISP maintains the actual connection to the Internet using its own router.

Connecting a LAN to the Internet requires that the devices on the LAN support the TCP/IP suite of protocols that provide the foundation of the Internet. At a minimum a computer accessing the Internet must have or be assigned an IP address, subnet mask, and default gateway. These protocols are necessary for computers on the LAN to be able to communicate with devices in other parts of the Internet. The TCP/IP suite of protocols include

- Simple Mail Transfer Protocol (SMTP) [RFC 821]—handles the transferring of e-mail messages
- Post Office Protocol (POP/POP3) [RFC1939]—facilitates e-mail drop services
- HyperText Transfer Protocol (HTTP) [RFC 2616]—facilitates the delivery of Web documents
- File Transfer Protocol (FTP) [RFC 959]—transfers files
- Telnet [RFC 854]—allows users to remotely connect to other computers over the Internet
- Secure shell (ssh) [RFC 4250]—allows users to securely connect to other computers over the Internet

Many organizations have set up their own internal Internet called an intranet. An intranet is a private network that uses the same protocols as the Internet. An intranet appears to the user like the Internet, but it is typically not open to anyone outside the organization. An intranet is not a replacement for a LAN, but rather runs within a LAN and supports many of the same applications as the Internet, typically Web servers and browsers, e-mail servers and clients, as well as additional groupware software. The core of most intranets is the Web site, which typically contains most of the internal documents that need to be disseminated among the organization's members. Setting up an intranet site on an organization's LAN requires a lot of organization and planning in selecting the hardware, software, and data needed to create a functional intranet.

Some organizations have taken the intranet concept one step further and link to external partners of the organization through the Internet via an extranet. An extranet is basically an intranet that may include access by customers, suppliers, and trusted partners.

WIRELESS LOCAL AREA NETWORKS

Wireless local area networks (WLANs) are rapidly becoming ubiquitous in both offices and homes. WLANs provide the freedom to access data without being tethered to the network with wires. WLANs enable users to take laptops and handheld computers anywhere, anytime and still be able to access the network. This is becoming more important in today's world of information.

Wireless networks are easier and less expensive to install. Most laptop and other portable devices can be purchased with a built-in WiFi card (wireless NIC). WiFi cards and USB WiFi devices can be installed with older laptops and desktop computers. Wireless networks require spending less money on cable and not needing to spend additional money and time installing the cable. Wireless access points and NICs have become more affordable in the past several years. Installing a wireless network involves turning on the access points, installing the software for the access points and NICs, and identifying the access points to which the NICs connect. Modifying a wireless network is easier, but does have its issues. There is no need to remove and/or relocate cable. There is no longer a concern for network cable failure.

Companies are using WLANs for keeping track of inventory in warehouses. Workers that need to be constantly in contact with their network are more frequently

- Transmission Control Protocol (TCP) [RFC 793]—establishes and maintains the Internet connection
- Internet Protocol (IP) [RFC 791]—handles the routing of packets of data across the Internet

using wireless LANs. WLAN devices have become commonplace among workers in the health care industry. One area where WLANs are beginning to have a great impact is in education. Students and faculty no longer need to find wired computer labs to communicate and work. With wireless devices, students and faculty can access the networks in any building where wireless access points have been installed.

Wireless networks still have some drawbacks. Chief among these drawbacks are the limitations on distance and bandwidth. The radius of a WLAN can be extended by adding additional access points and radiofrequency (RF) repeaters to the network. Adding additional access points on the same channel can also help optimize the use of the limited bandwidth of the WLAN. There are also standards and associated wireless devices that support increased bandwidth. Both standards 802.11b and 802.11g use the unlicensed 2.4 GHz ISM band, and support transmission speeds up to 11 Mbps and 54 Mbps respectively. The 2.4 GHz ISM band is also used by many cordless phones and other electronic home devices that can cause interference. A third standard—802.11a—uses the 5 GHz UNII band and supports transmission speeds up to 54 Mbps. If these devices are unable to communicate at the preferred speed, the devices will drop the speeds to optimize the communications. This often happens when there is interference in the communications from other devices. Changing the channels can often overcome this problem.

Several new standards are emerging that will increase the communications for WiFi networks. One of these is 802.11n. It is expected to replace current WiFi devices with ones that will be able to communicate at up to 250 Mbps. The standard 802.11n is based on multiple-input multiple-output (MIMO) technology where two or more radio antennas allow increased communications speeds.

The other major drawback for WLANs is security. A WLAN transmits radio signals over a broad area. This allows an intruder to lurk anywhere and intercept the signals from the wireless network. One way of inhibiting access to wireless network is to turn on encryption. By default, most wireless networks use Wired Equivalent Privacy (WEP). WEP relies on a secret key that is shared between a mobile station and the access point. The secret key is used to encrypt packets before they are transmitted, and an integrity check is used to ensure that packets are not modified in transit. WEP is easily compromised. Better security can be obtained by using WiFi Protected Access (WPA and WPA2) which uses a passphrase as a seed for the encryption. There are a variety of additional security measures that should be implemented to better secure the wireless network.

LAN INSTALLATION

Before a LAN is installed, a lot of planning needs to take place. The process can typically be broken down into seven steps:

- Needs analysis
- Site analysis

- Equipment selection
- Site design
- Server configuration
- Installation schedule
- Installation

Needs Analysis

The first aspect of installing a LAN is determining the needs of the organization and the users. Is a LAN needed? What aspects of the network are needed? Who will be using the network? What will they be using the network for? Will a LAN help the bottom line of the organization?

Reasons for installing a local area network might include:

- Need for improved communication
- Need for centralizing data
- Need for sharing hardware
- Need for application sharing
- Need for automating work flow
- Need for enhanced security of data

Site Analysis

Once a need has been established, it is necessary to determine where the LAN will be installed. What parts of the organization's site will be networked? Where will the servers be located? A site plan will need to be drawn. If a fire escape plan is available, it can be used as a template for the building and location of rooms and doors. It is best if the architectural plans can be found. The site plan (Figure 28) is a map of the location where the network is installed and should include:

- The dimensions of the site, including the location of each employee
- The location of all immovable objects, including doors and windows
- The current location of all moveable objects
- The location of heating, ventilation, and air conditioning systems and ducts
- The location of electrical outlets and the current wiring scheme
- The current location of all computer equipment and the planned location for any additional devices

Equipment Selection

As the site plan is developed, an inventory of equipment on hand needs to be conducted. An inventory of equipment will identify the capabilities of the equipment incorporated into the proposed network. This will identify which equipment will be obsolete once the network is installed and which equipment will require modification. Older workstations may still be useful as print servers. Table 2 shows a table of the features to be noted in the equipment survey.

Once the current equipment has been inventoried, it is now time to identify new equipment that will need to be

Figure 28: Sample site plan

Table 2: Equipment Inventory Form

Serial Number	XXXXXXXXXX
Processor	Pentium® 4 Processor 630 3.0GHz, 800MHz FSB
RAM size and configuration	2 GB DDR2 Non-ECC SDRAM 533 MHz
Hard disk	160GB SATA 7200RPM
Other drives	One 3.5", 1.44 MB
CD-ROM	48X CD-ROM Drive
Monitor	17" Flat Panel
Warranty information	Expires Jan. 2008

purchased. This list should be correlated with the user needs identified earlier. Once this list is prepared, vendors can be contacted, soliciting their recommendations for meeting the hardware and software needs. Be sure to consider any infrastructure constraints including electrical power and distances. Table 3 is an example of a form that could be used to compare different vendor proposals.

An important consideration is whether the network is completely wired, completely wireless, or a hybrid of the two. This will depend on the site analysis and the needs of the organization.

Site Design

Once the site plan from the site analysis has been completed and the equipment lists have been completed, it is time to create a working site design (Figure 29). This design will include details of where all devices including networking devices will be located. The location for all network connections must be indicated. The location of all network cable, patch panels, and riser backbone must be delineated.

Server Configuration

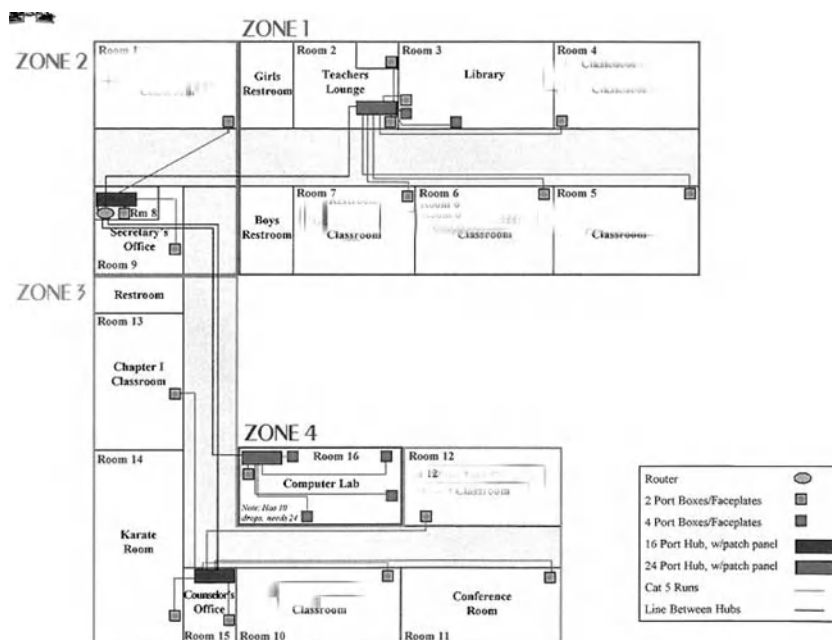

Once the computers arrive that will be installed as servers, they need to be configured. Server software needs to be installed and the directory structure of the server needs to be organized. The directory structure begins with the root directory with all other directories within it and the files and subdirectories within those. Typically, you will have directories for the network operating system, separate directories for each server application, and directories for the clients who will be connecting to the server. Network information including MAC and IP addresses for all devices needs to be recorded.

Installation Schedule

Networks take a considerable amount of time to install. It is important to have an installation schedule. There will be times when employees' computers will need to be turned off and possibly moved. Disruption needs to be minimized wherever possible. Be sure to include in the installation schedule the possibility for shipping delays on the equipment that has been ordered. Be sure to read

the manuals before the installation begins so that there will not be any surprises once the installation starts. Also prepare the site before the installation begins. This may involve moving furniture, installing new outlets, and removing equipment that will no longer be used. Don't forget to back up any data that is on systems that will be affected by the move.

Installation

Before the installation begins, it is best to discuss everything with someone who has been through a LAN

installation before. Have this person look over the designs, schedules, and forms to ensure that nothing was forgotten. Depending on the size of the installation, it may take anywhere from a couple hours to a couple of days. Be prepared for delays. If this is a wired network, conduit may need to be installed and the cable media will need to be pulled. This is the part that typically takes the longest time. While the cable media is being pulled or shortly thereafter, the remaining components will need to be installed. This would typically include the patch panels in the communications rooms and the wall outlets for each device that will be networked (Figure 30). Once

Figure 30: Configuration of wiring closet

this is completed, the electronic devices (hubs, switches, etc.) will need to be installed. If network cards need to be installed in the older computers, this will be done next. Finally, the software for the network cards will need to be installed on each workstation and server if it hasn't already been done. Be sure to install the appropriate network software.

The final two stages of the installation are the testing and training. Every device will need to be tested to ensure that its network connection works. This should be done before any of the users access the network. Be sure to test all of the network devices and the networked printers. Applications, service, and end-to-end testing must be performed. It is imperative that the security analysis of the network, including the wireless components, be conducted. The final phase is training. Users will need to be trained in the procedures they will need to follow to use the network.

LAN ADMINISTRATION

Once the LAN has been installed, there are several key aspects of administering the network.

Configuration List

Using the equipment inventory forms developed during the installation along with similar documentation for the new devices, a set of configuration lists needs to be developed. These would include a list of all computers similar to the equipment inventory form, directory lists for each server that is installed, a list of all server users, a list of all printers and other shared devices. It is also very important to keep copies of the network plans developed for the installation of the network.

System Log

The system log is documentation for the network. It provides a detailed history of the network's hardware, software, and configuration features. As changes are made to the network, these changes need to be documented in the system log. As problems arise with the network, these also need to be documented in the system log. This log needs to be maintained from the beginning. The system log should include all hardware and software warranties,

hardware and software information, current setup structure, backup and recovery plan, backup logs, and error/downtime logs.

Training

Training doesn't end after the network has been installed. The network is a dynamic part of an organization's computing system. As changes are made, employees will need additional training.

Backup

As more and more data is kept on networked servers and shared by more than one user, it becomes critical that a procedure be established for backing up critical data. This may be the most important task for a network administrator. Hardware and software can be replaced. New employees can be hired. But it is difficult to recreate large amounts of data. The network administrator must establish a schedule for backing up all critical data. Separate storage area network (SAN) or networked attached storage (NAS) may be needed to provide added storage protection. Critical software may not necessarily be replaced and should be backed up as well. Configuration files on all servers should be backed up.

Security

Once computers become accessible to other individuals, security issues need to be considered. In a networked environment, users will need user IDs and passwords. If security is extremely important, then encryption of data might also need to be implemented. If the local area network is attached to another network, then a firewall may be necessary to control access to critical data between the two networks.

LAN SECURITY

In today's world of ubiquitous local area networks, security is of the utmost importance. This is true whether the LAN is a peer-to-peer or client/server network. Security is all about confidentiality, integrity, and availability. Where necessary, information should be confidential. The information should be only available to those who are authorized

to access it. The integrity of the information must be maintained. We need to be assured that the information has not been altered. The availability of the information must be preserved. Authorized users need to be able to access the information and computing resources when needed.

Securing a LAN requires a multilayered approach. One of the main themes in security is “defense in depth” where multiple layers of technology and multiple procedures need to be implemented to minimize the threats to the local area network.

Physical Security

“I touch it, I own it!” Without physical security, there is no security. Having physical access to the devices and computers on a network is the greatest vulnerability in network security. No matter how strong other facets of security, if an attacker can physically access computers and other devices, the LAN can be easily compromised.

All LAN servers must be locked in a physically secure area. Network devices and cable need to be protected from intentional and unintentional disruption. To avoid inadvertent compromises, servers should not be used as client workstations. It is too easy for client-based vulnerabilities to be compromised and affect the server software running on the same computer. Securing a LAN includes more than preventing attacks. An inadvertent loss of power to the computers and network devices can be catastrophic. All devices should be protected by surge protectors. Power to servers and other critical hardware needs to be stabilized using uninterruptible power supplies (UPS). The UPS battery needs to be checked regularly. An alternate power supply, such as a generator or second utility grid should be available for mission-critical LANs.

Access Security

The first line of defense is access control. Access to servers and the data needs to be controlled. This can be implemented by instituting controls at the network level as well as individual controls at the directory and file levels. Connections to all servers and the network should be controlled through authentication procedures. All users must be registered and authenticated. There should be no guest accounts. Minimally the use of user IDs and passwords should be required for all connections to the network. All users need to use nontrivial passwords that are difficult to “guess.” This includes using passwords that are sufficiently long and not using words that would be found in dictionaries or other wordlists. These passwords should be frequently changed and checked. Unfortunately, too many passwords can create operational issues. Often times, users will forget their passwords. A mechanism needs to be in place to address this problem. All default passwords for servers, operating systems, and applications must be changed immediately. All obsolete user accounts need to be terminated immediately. It may also be necessary to restrict user access to certain days and times to better control access to sensitive data.

There should be several levels of access to directories and files. These typically would include read, write, and

execute. Users need to be given the minimum privileges to access all their files and directories. All data must be protected from access by unauthorized users. It is important that authorization is carefully planned. Audit logs of successful and unsuccessful access to systems and files may need to be kept to allow for tracking of problems that arise.

Data Security

Where necessary, critical data needs to be protected. In addition to those mechanisms discussed above, additional layers of security may be necessary. In the case of databases, views need to be provided to permit users to access only the minimum that is necessary.

Data confidentiality is especially important. Where necessary, encryption software needs to be used to protect confidential and sensitive data. Controls need to be implemented to protect all confidential and sensitive data stored and/or processed on the LAN. These controls should include any removable media associated with the LAN. It is important that all confidential and sensitive data be removed before disposing of the media that the data resides on. Remember that simply deleting a file that contains the data may not be enough. Be sure to delete any copies of the files stored on backup media and “empty the trash.”

Backup procedures need to be implemented. All files servers need to be automatically backed up on a regularly scheduled basis. The backup media needs to be kept onsite for immediate recovery. Copies of the backup media need to be kept off-site in case the onsite backups are compromised. Both sets of backups need to be tested and audited to ensure recovery.

Network Security

There are two major approaches to securing a local area network: host-based security and network-based security. Typically, both approaches are combined to provide multiple levels of security.

In host-based security, selected hosts are separately protected. This could range from installing antivirus software and personal firewalls on each computer in the network, to installing a host-based intrusion detection system on each server. Minimally, every server should be protected with antivirus software and a personal firewall. If possible, the important servers should also be shielded by a host-based intrusion detection system.

Network-based security is equally important. Hardware-based security devices such as firewalls and intrusion detection devices can be placed at the perimeter of the network, typically inside the router where they can monitor all traffic coming in and out of the local area network. Intrusion detection and intrusion protection devices can also be set up with agents installed on those hosts needing the most protection. These agents can then be monitored and managed from a central location. In more secure environments, there may be layers of network-based security both at the perimeter of the LAN as well as internal to the network. One layer of security is the placement of a firewall device (Figure 31) between the LAN (trusted network) and the outside (untrusted networks).

Figure 31: Placement of a firewall

The network should be audited for illicit use of inappropriate software (e.g., sniffers, traffic monitors.) No unauthorized connections to the network should be permitted. This would include rogue wireless access points and modems connections.

Malware

Malware includes programs like viruses, worms, and spyware. To protect against most malware attacks, antivirus software needs to be installed on all servers and clients. It is imperative that this software be kept up to date on all computers. Most antivirus software vendors have procedures for automatically updating the software. The auto-update feature should be configured to the shortest time that is tolerable by the users. All foreign media and all files downloaded from the Internet must be scanned for malware. The antivirus software needs to be running continuously. In addition to updating the antivirus software, it is mandatory that all operating systems and applications running on all computers in the network be patched. "Patching host software is probably the single most important thing companies can do to improve their security" (Panko, 2004). Software vulnerabilities are constantly being exposed. Threats that exploit these vulnerabilities are rapidly developed and can best be prevented from compromising the system's security by downloading security patches as soon as the patches are available. Users should be trained in how to disconnect their device from the network in the event of a virus attack to isolate their host. One vulnerability in an operating system or application can destroy the entire network of computers.

Policy, Procedures, and Awareness

"Security is not a product, it's a process" (Schneier, 1999). Using any security product without understanding what it does, and what it does not protect against is a recipe for disaster. Keep in mind that added security features tend to increase the complexity of the system and may decrease

the degree of usability of the systems. Usability needs to be balanced with the increased need for security.

Any organization implementing or using a LAN must have a well-documented security policy. The policy should incorporate physical security procedures, email, Internet acceptable usage, and network usage procedures. The policy should include procedures for incident response and a LAN risk analysis. The policy should include a focus on software use to ensure compliance with license agreements. All unauthorized copies of software should be removed from workstations and servers. The policy needs to outline what additional response is necessary when unauthorized software is discovered.

The policy must include procedures for ensuring that all software is patched on a regular basis. This is especially important for all security software including antivirus software and any intrusion detection and prevention software protecting the LAN and its resources.

As mentioned earlier, audit logs need to be invoked. These logs should not only document successful and unsuccessful access to resources on the LAN, but should record any and all anomalies. These audit logs must be reviewed regularly with procedures in place for addressing any security alerts or identified anomalies. All attacks and breaches of security need to be investigated immediately and followed up with appropriate responses.

"The most potent tool in any security arsenal isn't a powerful firewall or a sophisticated intrusion detection system. When it comes to security, knowledge is the most effective tool..." (Schweizer, 2003). There needs to be a regular training program for administration and users. Administrators need to be trained on their responsibilities in managing the security of the LAN and its components. Regular security awareness sessions need to be scheduled and required for all employees including training against social engineering attacks. An important policy is to train before deploying any component in the network.

CONCLUSION

LANs play a very important role in providing computer resources to large numbers of users. They allow users to share hardware, software, and most importantly data. They also provide access to the Internet as well as organization intranets and extranets. With the emergence of WANs, the applications of LANs will continue to expand. It is imperative that we secure the LANs to ensure confidentiality, integrity, and availability of the data.

GLOSSARY

Access point: is a hardware device consisting of one or more antennae, a radio transmitter, and a wired network interface. Used as a bridge between a wireless network and a wired network. The access point acts a hub for the wireless network.

Attenuation: is a loss of energy from a signal as a result of resistance in the medium.

Bridge: is a network device for connecting two or more local area networks that typically use different media but the same network protocol.

Bus network: refers to a network where the nodes are connected to the same wire. Data is broadcast from one node to all other nodes in the LAN even though the data may be intended for only one node.

Ethernet: is a common data-link layer technology for networking computers in a LAN using the CSMA/CD access method.

Extranet: is a private portion of the Internet treated as an extension of an organization's intranet and allowing access to the organization's data by the organization's partners, customers, and so on.

Fiber-Distributed Data Interface (FDDI): data-link layer standard based on token ring for extended data communications using optical fiber.

Hub: is the central device in a star network for connecting multiple nodes to a network. It functions as a multiple point repeater.

IEEE 802.3: is a collection of standards for CSMA/CD (Ethernet)-based LANs.

IEEE 802.5: is a collection of standards for token ring-based LANs.

IEEE 802.11: is a collection of standards for wireless-based LANs.

Internet: is a worldwide collection of networks linked together and built around the TCP/IP suite of protocols. It was originally conceived in 1969 by the Advanced Research Projects Agency (ARPA) of the U.S. government.

Intranet: is an organization's private internal network based on the TCP/IP suite of protocols.

Local area network (LAN): is a data communication network of computers, peripheral devices, and other network devices allowing data to be communicated at high speeds over short distances.

Logical topology: or electrical topology is based on how the devices of the network are electrically configured.

Network: is an interconnection of two or more computers or devices.

Network interface card (NIC): is an adapter for connecting a computer or device to the network media.

Personal area network (PAN): is a communication network of computing devices within close proximity of a person typically a few meters.

Physical topology: is based on the way the nodes are physically configured in the network.

Repeater: is a network device that retransmits the communication signal and is used for extending the radius of a network. It operates at the OSI physical layer.

Ring network: refers to a network where the nodes are arranged in a closed loop where each device is connected directly to two adjacent devices.

Router: is a special-purpose network device that connects two or more networks at the OSI network layer.

Social engineering: is the process of compromising a computer system and/or its data by manipulating the users.

Star network: has the nodes arranged so that each device is connected to a central device, typically a hub or a switch.

Switch: is a network device operating at the OSI data-link layer that connects multiple network segments. It functions as a multiport bridge, allowing two devices to communicate only with each other at that moment.

Wide area network (WAN): is a data communication network spanning geographically dispersed areas.

TRADITIONAL ETHERNET

The original commercial Ethernet, as well as the original Institute of Electrical and Electronics Engineers (IEEE) 802.3 standard, operated at 10 Mbps, and there are still a number of 10-Mbps Ethernet LANs in use. In recent years, standards have been developed for 802.3 systems operating at 100 Mbps, 1 Gbps, and 10 Gbps. Before looking at these high-speed LANs, we provide a brief overview of the original 10-Mbps Ethernet and introduce the concept of switched LANs.

Classical Ethernet operates at 10 Mbps over a bus topology LAN using the CSMA/CD media access control protocol. In this section, we introduce the concepts of bus LANs and CSMA/CD operation, and then briefly discuss transmission medium options.

Bus Topology LAN

In a bus topology LAN, all stations attach, through appropriate hardware interfacing known as a tap, directly to a linear transmission medium, or bus. Full-duplex operation between the station and the tap allows data to be transmitted onto the bus and received from the bus. A transmission from any station propagates the length of the medium in both directions and can be received by all other stations. At each end of the bus is a terminator, which absorbs any signal, removing it from the bus.

Two problems present themselves in this arrangement. First, because a transmission from any one station can be received by all other stations, there needs to be some way of indicating for whom the transmission is intended. Second, a mechanism is needed to regulate transmission. To see the reason for this, consider that if two stations on the bus attempt to transmit at the same time, their signals will overlap and become garbled. Or consider that one station decides to transmit continuously for a long period of time, blocking the access of other users.

To solve these problems, stations transmit data in small blocks, known as frames. Each frame consists of a portion of the data that a station wishes to transmit, plus a frame header that contains control information. Each station on the bus is assigned a unique address, or identifier, and the destination address for a frame is included in its header.

Figure 1 illustrates the scheme. In this example, station C wishes to transmit a frame of data to A. The frame header includes A's address. As the frame propagates

along the bus, it passes B. B observes the address and ignores the frame. A, on the other hand, sees that the frame is addressed to itself and therefore copies the data from the frame as it goes by.

So the frame structure solves the first problem mentioned previously: It provides a mechanism for indicating the intended recipient of the data. It also provides the basic tool for solving the second problem, the regulation of access. In particular, the stations take turns sending frames in some cooperative fashion, as explained in the next subsection.

Media Access Control

For CSMA/CD, a station wishing to transmit first listens to the medium to determine if another transmission is in progress (carrier sense). If the medium is idle, the station may transmit. It may happen that two or more stations attempt to transmit at about the same time. If this happens, there will be a collision; the data from both transmissions will be garbled and not received successfully. The following procedure specifies what a station should do if the medium is found busy and what it should do if a collision occurs:

1. If the medium is idle, transmit; otherwise, go to step 2.
2. If the medium is busy, continue to listen until it is idle, then transmit immediately.
3. If a collision is detected during transmission, transmit a brief jamming signal to assure that all stations know that there has been a collision and then cease transmission.
4. After transmitting the jamming signal, wait a random amount of time, referred to as the backoff, then attempt to transmit again (repeat from step 1).

Figure 2 illustrates the technique. The upper part of the figure shows a bus LAN layout. The remainder of the figure depicts activity on the bus at four successive instants in time. At time t_0 , station A begins transmitting a packet addressed to D. At t_1 , both B and C are ready to transmit. B senses a transmission and so defers. C, however, is still unaware of A's transmission and begins its own transmission. When A's transmission reaches C, at t_2 , C detects the collision and ceases transmission. The effect of the collision propagates back to A, where it is detected some time later, t_3 , at which time A ceases transmission.

Figure 1: Frame transmission on a bus LAN

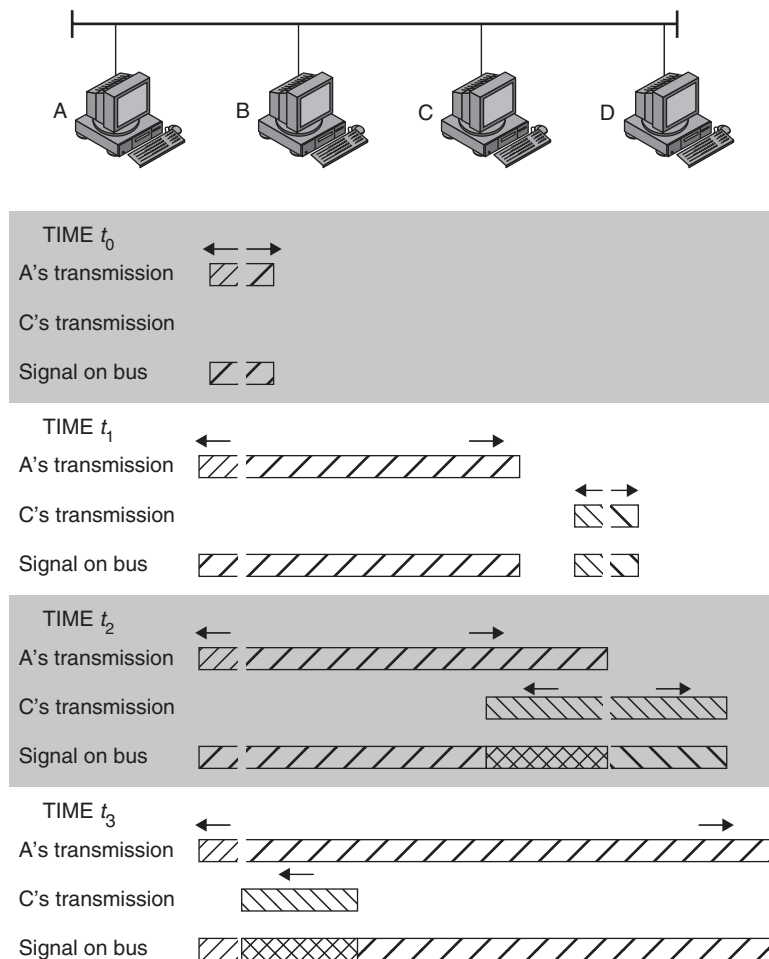

Figure 2: CSMA/CD operation

When a collision occurs, IEEE 802.3 systems use an algorithm called binary exponential backoff to calculate the random amount of time the sender must wait before attempting to retransmit the frame. For each of the retransmissions, the algorithm doubles the range of the random delay. Thus, after n collisions, the system will wait for a random amount of time, in the range from 0 to $2n$ to 1 units of time before attempting to retransmit the frame.

The advantage of CSMA/CD is its simplicity. It is easy to implement the logic required for this protocol. Furthermore, there is little to go wrong in the execution of the protocol. For example, if for some reason a station fails to detect a collision, the worst that can happen is that it continues to transmit its frame, wasting some time on the medium. Once the transmission is over, the algorithm continues to function as before.

MAC Frame

Figure 3 depicts the frame format for the 802.3 protocol. It consists of the following fields:

- **Preamble:** A 7-octet pattern of alternating 0s and 1s used by the receiver to establish bit synchronization.
- **Start Frame Delimiter (SFD):** The sequence 10101011, which indicates the actual start of the frame and enables the receiver to locate the first bit of the rest of the frame.
- **Destination Address (DA):** Specifies the station(s) for which the frame is intended. It may be a unique physical address, a group address, or a global address.
- **Source Address (SA):** Specifies the station that sent the frame.
- **Length:** Length of Logical Link Control (LLC) data field in octets. The maximum frame size, excluding the Preamble and SFD, is 1518 octets.
- **LLC Data:** Data unit supplied by LLC.
- **Pad:** Octets added to ensure that the frame is long enough for proper CD operation.
- **Frame Check Sequence (FCS):** A 32-bit cyclic redundancy check (CRC), based on all fields except preamble, SFD, and FCS.

IEEE 802.3 Medium Options at 10 Mbps

The IEEE 802.3 committee has defined a number of alternative physical configurations. This is both good and bad. On the good side, the standard has been responsive to evolving technology. On the bad side, the customer, not

to mention the potential vendor, is faced with a bewildering array of options. However, the committee has been at pains to ensure that the various options can be easily integrated into a configuration that satisfies a variety of needs. Thus, the user who has a complex set of requirements may find the flexibility and variety of the 802.3 standard to be an asset.

To distinguish the various implementations that are available, the committee has developed a concise notation:

<data rate in Mbps> <signaling method> <maximum segment length in hundreds of meters>

The defined alternatives are:

- **10BASE5:** Specifies the use of 50-ohm coaxial cable and Manchester digital signaling. The maximum length of a cable segment is set at 500 meters (m). The length of the network can be extended by the use of repeaters. A repeater is transparent to the media access control MAC level; as it does no buffering, it does not isolate one segment from another. So, for example, if two stations on different segments attempt to transmit at the same time, their transmissions will collide. To avoid looping, only one path of segments and repeaters is allowed between any two stations. The standard allows a maximum of four repeaters in the path between any two stations, extending the effective length of the medium to 2.5 kilometers (km).
- **10BASE2:** Similar to 10BASE5 but uses a thinner cable, which supports fewer taps over a shorter distance than the 10BASE5 cable. This is a lower-cost alternative to 10BASE5.
- **10BASE-T:** Uses unshielded twisted pair in a star-shaped topology. Because of the high data rate and the poor transmission qualities of unshielded twisted pair, the length of a link is limited to 100 m. As an alternative, an optical fiber link may be used. In this case, the maximum length is 500 m.
- **10BASE-F:** Contains three specifications: a passive-star topology for interconnecting stations and repeaters with up to 1 km per segment; a point-to-point link that can be used to connect stations or repeaters at up to 2 km; a point-to-point link that can be used to connect repeaters at up to 2 km.

Note that 10BASE-T and 10BASE-F do not quite follow the notation: “T” stands for twisted pair and “F” stands

Figure 3: IEEE 802.3 frame format

Table 1: IEEE 802.3 10-Mbps physical layer medium alternatives

	10BASE5	10BASE2	10BASE-T	10BASE-FP
Transmission medium	Coaxial Cable (50 ohm)	Coaxial Cable (50 ohm)	Unshielded twisted pair	850-nm optical fiber pair
Signaling technique	Baseband (Manchester)	Baseband (Manchester)	Baseband (Manchester)	Manchester/On-off
Topology	Bus	Bus	Star	Star
Maximum segment length (m)	500	185	100	500
Nodes per segment	100	30	—	33
Cable diameter (mm)	10	5	0.4 to 0.6	62.5/125 μ m

for optical fiber. Table 1 summarizes the preceding options. All of the alternatives listed in the table specify a data rate of 10 Mbps. In addition to these alternatives, there are versions that operate at 100 Mbps, 1 Gbps, and 10 Gbps; these are covered later in this section.

HIGH-SPEED ETHERNET

Fast Ethernet

If one were to design a high-speed (100 Mbps or more) LAN from scratch, one would not choose CSMA/CD as the basis for the design. CSMA/CD is simple to implement and robust in the face of faults. However, it does not scale well. As the load on a bus increases, the number of collisions increases, degrading performance. Furthermore, as the data rate for a given system increases, performance also decreases. The reason for this is that at a higher data rate, a station can transmit more bits before it recognizes a collision, and therefore more wasted bits are transmitted.

These problems can be overcome. To accommodate higher loads, a system can be designed to have a number of different segments, interconnected with hubs. The hubs can act as barriers, separating the LAN into collision domains, so that a collision in one domain does not spread to other domains. The use of switched Ethernet hubs in effect eliminates collisions, further increasing efficiency.

At this point, we need a brief digression to explain the difference between a simple (dumb) hub and a switching hub. In both cases, multiple end systems are attached to the hub. In the case of a simple hub, a transmission from any one station is received by the hub and retransmitted on all of the outgoing lines. Therefore, to avoid collisions, only one station should transmit at a time. In the case of a switching hub, the central hub acts as a switch, similar to a packet switch. An incoming frame from a particular station is switched to the appropriate output line to be delivered to the intended destination. At the same time, other unused lines can be used for switching other traffic.

Despite some drawbacks to its use, Ethernet-style LANs have been developed that operate at 100 Mbps, 1 Gbps, and 10 Gbps. The reasons for this are instructive. From the vendor's point of view, the CSMA/CD protocol is well understood and vendors have experience building the hardware, firmware, and software for such systems. Scaling the

system up to 100 Mbps or more may be easier than implementing an alternative protocol and topology. From the customer's point of view, it is relatively easy to integrate older systems running at 10 Mbps with newer systems running at higher speeds if all the systems use the same frame format and the same access protocol. In other words, the continued use of Ethernet-style systems is attractive because Ethernet is already there. This same situation is encountered in other areas of data communications. Vendors and customers do not always, or even in the majority of cases, choose the technically superior solution. Cost, ease of management, and other factors relating to the already-existing base of equipment are more important factors in the selection. This is the reason that Ethernet-style systems continue to dominate the LAN market long after most observers predicted the demise of Ethernet.

Fast Ethernet refers to a set of specifications developed by the IEEE 802.3 committee to provide a low-cost, Ethernet-compatible LAN operating at 100 Mbps. The blanket designation for these standards is 100BASE-T. The committee defined a number of alternatives to be used with different transmission media.

Table 2 summarizes key characteristics of the 100BASE-T options. All of the 100BASE-T options use the IEEE 802.3 MAC protocol and frame format. 100BASE-X refers to a set of options that use the physical medium specifications. All of the 100BASE-X schemes use two physical links between nodes; one for transmission and one for reception. 100BASE-TX makes use of shielded twisted pair (STP) or high-quality (Category 5) unshielded twisted pair (UTP). 100BASE-FX uses optical fiber; this option is being phased out in favor of faster fiber-based technologies.

In many buildings, any of the 100BASE-X options requires the installation of new cable. For such cases, 100BASE-T4 defines a lower-cost alternative that can use Category 3, voice-grade UTP in addition to the higher-quality Category 5 UTP. To achieve the 100-Mbps data rate over lower-quality cable, 100BASE-T4 dictates the use of four twisted-pair lines between nodes, with the data transmission making use of three pairs in one direction at a time. This option is rarely used.

For all of the 100BASE-T options, the topology is similar to that of 10BASE-T, namely a star-wire topology.

Table 2: IEEE 802.3 100BASE-T physical layer medium alternatives

	100BASE-TX		100BASE-FX	100BASE-T4
Transmission medium	2 pair, STP	2 pair, Category 5 UTP	2 optical fibers	4 pair, Category 3, 4, or 5 UTP
Signaling technique	MLT-3	MLT-3	4B5B, NRZI	8B6T, NRZ
Data rate	100 Mbps	100 Mbps	100 Mbps	100 Mbps
Maximum segment length	100 m	100 m	100 m	100 m
Network span	200 m	200 m	400 m	200 m

100BASE-X

For all of the transmission media specified under 100BASE-X, a unidirectional data rate of 100 Mbps is achieved transmitting over a single link (single twisted pair, single optical fiber). For all of these media, an efficient and effective signal encoding scheme is required. The one chosen is referred to as 4B/5B-NRZI. This scheme is further modified for each option.

The 100BASE-X designation includes two physical medium specifications, one for twisted pair, known as 100BASE-TX, and one for optical fiber, known as 100BASE-FX.

100BASE-TX makes use of two pairs of twisted-pair cable, one pair used for transmission and one for reception. Both STP and Category 5 UTP are allowed. The MTL-3 signaling scheme is used.

100BASE-FX makes use of two optical fiber cables, one for transmission and one for reception. With 100BASE-FX, a means is needed to convert the 4B/5B-NRZI code group stream into optical signals. The technique used is known as intensity modulation. A binary 1 is represented by a burst or pulse of light; a binary 0 is represented by either the absence of a light pulse, or a light pulse at very low intensity.

100BASE-T4

100BASE-T4 is designed to produce a 100-Mbps data rate over lower-quality Category 3 cable, thus taking advantage of the large installed base of Category 3 cable in office buildings. The specification also indicates that the use of Category 5 cable is optional. 100BASE-T4 does not transmit a continuous signal between packets, which makes it useful in battery-powered applications.

For 100BASE-T4 using voice-grade Category 3 cable, it is not reasonable to expect to achieve 100 Mbps on a single twisted pair. Instead, 100BASE-T4 specifies that the data stream to be transmitted is split up into three separate data streams, each with an effective data rate of 33.5 Mbps. Four twisted pairs are used. Data are transmitted using three pairs and received using three pairs. Thus, two of the pairs must be configured for bidirectional transmission.

As with 100BASE-X, a simple NRZ encoding scheme is not used for 100BASE-T4. This would require a signaling rate of 33 Mbps on each twisted pair and does not provide synchronization. Instead, a ternary signaling scheme known as 8B6T is used.

Full-Duplex Operation

A traditional Ethernet is half duplex: a station can either transmit or receive a frame, but it cannot do both simultaneously. With full-duplex operation, a station can transmit and receive simultaneously. If a 100-Mbps Ethernet ran in full-duplex mode, the theoretical transfer rate becomes 200 Mbps.

Several changes are needed to operate in full-duplex mode. The attached stations must have full-duplex rather than half-duplex adapter cards. The central point in the star wire cannot be a simple multiport repeater but rather must be a switching hub. In this case each station constitutes a separate collision domain. In fact, there are no collisions and the CSMA/CD algorithm is no longer needed. However, the same 802.3 MAC frame format is used and the attached stations can continue to execute the CSMA/CD algorithm, even though no collisions can ever be detected.

Mixed Configuration

One of the strengths of the Fast Ethernet approach is that it readily supports a mixture of existing 10-Mbps LANs and newer 100-Mbps LANs. For example, the 100-Mbps technology can be used as a backbone LAN to support a number of 10-Mbps hubs. Many of the stations attach to 10-Mbps hubs using the 10BASE-T standard. These hubs are in turn connected to switching hubs that conform to 100BASE-T and that can support both 10-Mbps and 100-Mbps links. Additional high-capacity workstations and servers attach directly to these 10/100 switches. These mixed-capacity switches are in turn connected to 100-Mbps hubs using 100-Mbps links. The 100-Mbps hubs provide a building backbone and are also connected to a router that provides connection to an outside WAN.

Gigabit Ethernet

In late 1995, the IEEE 802.3 committee formed a High-Speed Study Group to investigate means for conveying packets in Ethernet format at speeds in the gigabits per second range. A set of 1000-Mbps standards has since been issued. There are many forces driving demand for greater transmission capacity to the desktop. Gigabit Ethernet is moving to the desktop as demands for streaming multimedia, remote processing, videogaming, videoconferencing with concurrent video streams, and multitasking processes demand increased bandwidth.

The strategy for Gigabit Ethernet is the same as that for Fast Ethernet. Although defining a new medium and transmission specification, Gigabit Ethernet retains the CSMA/CD protocol and frame format of its 10-Mbps and 100-Mbps predecessors. It is compatible with 100BASE-T and 10BASE-T, preserving a smooth migration path. As more organizations move to 100BASE-T, putting huge traffic loads on backbone networks, demand for Gigabit Ethernet has intensified.

Media Access Layer

The 1000-Mbps specification calls for the same CSMA/CD frame format and MAC protocol as used in the 10-Mbps and 100-Mbps version of IEEE 802.3. For shared-medium hub operation, there are two enhancements to the basic CSMA/CD scheme:

- **Carrier extension:** Carrier extension appends a set of special symbols to the end of short MAC frames so that the resulting block is at least 4096 bit-times in duration, up from the minimum 512 bit-times imposed at 10 and 100 Mbps. This is so that the frame length of a transmission is longer than the propagation time at 1 Gbps.
- **Frame bursting:** This feature allows for multiple short frames to be transmitted consecutively, up to a limit, without relinquishing control for CSMA/CD between frames. Frame bursting avoids the overhead of carrier extension when a single station has a number of small frames ready to send.

With a switching hub, which provides dedicated access to the medium, the carrier extension and frame bursting features are not needed. This is because data transmission and reception at a station can occur simultaneously

without interference and with no contention for a shared medium.

Physical Layer

The current 1-Gbps specification for IEEE 802.3 includes the following physical layer alternatives (Figure 4):

- **1000BASE-SX:** This short-wavelength option supports duplex links of up to 275 m using 62.5- μ m multimode or up to 550 m using 50- μ m multimode fiber. Wavelengths are in the range of 770 to 860 nm.
- **1000BASE-LX:** This long-wavelength option supports duplex links of up to 550 m of 62.5- μ m or 50- μ m multimode fiber or 5 km of 10- μ m single-mode fiber. Wavelengths are in the range of 1270 to 1355 nm.
- **1000BASE-CX:** This option supports 1-Gbps links among devices located within a single room or equipment rack, using copper jumpers (specialized STP cable that spans no more than 25 m). Each link is composed of a separate STP running in each direction.
- **1000BASE-T:** This option makes use of four pairs of Category 5 UTP to support devices over a range of up to 100 m.

The signal encoding scheme used for the first three Gigabit Ethernet options just listed is 8B/10B. The signal encoding scheme used for 1000BASE-T is 4D-PAM5, a relatively complicated scheme whose description is beyond our scope.

10-Gbps Ethernet

With gigabit products still fairly new, attention has turned in the past several years to a 10-Gbps Ethernet capability. The principal driving requirement for 10-Gigabit Ethernet is the increase in Internet and intranet

Figure 4: Gigabit Ethernet medium options (log scale)

traffic. A number of factors contribute to the explosive growth in both Internet and intranet traffic:

- An increase in the number of network connections
- An increase in the connection speed of each end-station (e.g., 10-Mbps users moving to 100 Mbps, analog 56-kbps users moving to DSL and cable modems)
- An increase in the deployment of bandwidth-intensive applications such as high-quality video
- An increase in Web hosting and application hosting traffic

Initially, network managers will use 10-Gbps Ethernet to provide high-speed, local backbone interconnection between large-capacity switches. As the demand for bandwidth increases, 10-Gbps Ethernet will be deployed throughout the entire network and will include server farm, backbone, and campus-wide connectivity. This technology enables Internet service providers (ISPs) and network service providers (NSPs) to create very high-speed links at a low cost, between co-located, carrier-class switches and routers.

The technology also allows the construction of metropolitan area networks (MANs) and WANs that connect geographically dispersed LANs between campuses or points of presence (PoPs). Thus, Ethernet begins to compete with asynchronous transfer mode (ATM) and other wide area transmission and networking technologies. In most cases where the customer requirement is data and TCP/IP transport, 10-Gbps Ethernet provides substantial value over ATM transport for both network end users and service providers:

- No expensive, bandwidth-consuming conversion between Ethernet packets and ATM cells is required; the network is Ethernet, end to end.
- The combination of IP and Ethernet offers quality of service and traffic policing capabilities that approach those provided by ATM, so that advanced traffic

engineering technologies are available to users and providers.

- A wide variety of standard optical interfaces (wavelengths and link distances) have been specified for 10-Gbps Ethernet, optimizing its operation and cost for LAN, MAN, or WAN applications.

The goal for maximum link distances encompasses a range of applications: from 300 m to 40 km. The links operate in full-duplex mode only, using a variety of optical fiber physical media.

Four physical layer options are defined for 10-Gbps Ethernet (Figure 5). The first three of these have two suboptions: an “R” suboption and a “W” suboption. The R designation refers to a family of physical layer implementations that use a signal encoding technique known as 64B/66B. The R implementations are designed for use over dark fiber, meaning a fiber-optic cable that is not in use and that is not connected to any other equipment. The W designation refers to a family of physical layer implementations that also use 64B/66B signaling but that are then encapsulated to connect to SONET equipment.

The four physical layer options are:

- 10GBASE-S (short): Designed for 850-nm transmission on multimode fiber. This medium can achieve distances up to 300 m. There are 10GBASE-SR and 10GBASE-SW versions.
- 10GBASE-L (long): Designed for 1310-nm transmission on single-mode fiber. This medium can achieve distances up to 10 km. There are 10GBASE-LR and 10GBASE-LW versions.
- 10GBASE-E (extended): Designed for 1550-nm transmission on single-mode fiber. This medium can achieve distances up to 40 km. There are 10GBASE-ER and 10GBASE-EW versions.
- 10GBASE-LX4: Designed for 1310-nm transmission on single-mode or multimode fiber. This medium can

Figure 5: 10-Gbps Ethernet distance options (log scale)

achieve distances up to 10 km. This medium uses wavelength-division multiplexing (WDM) to multiplex the bit stream across four light waves. LX-4 can transmit 10 Gbps over legacy or existing 1-Gbps multimode fiber and single-mode fiber infrastructure. In fact, installations of LX4 are possible over installed 100 Mbps fiber. This can prove to be an excellent upgrade value.

The success of fast Ethernet, Gigabit Ethernet, and 10-Gbps Ethernet highlights the importance of network management concerns in choosing a network technology. Both ATM and fiber channel, explored later, may be technically superior choices for a high-speed backbone, because of their flexibility and scalability. However, the Ethernet alternatives offer compatibility with existing installed LANs, network management software, and applications. This compatibility has accounted for the survival of a nearly 30-year-old technology (CSMA/CD) in today's fast-evolving network environment.

GLOSSARY

Carrier sense multiple access (CSMA): A media access control technique for multiple-access transmission media. A station wishing to transmit first senses the medium and transmits only if the medium is idle.

Carrier sense multiple access with collision detection (CSMA/CD): A refinement of CSMA in which a station ceases transmission if it detects a collision.

Collision: A condition in which two packets are being transmitted over a medium at the same time. Their interference makes both unintelligible.

Ethernet: The name given to a family of local area network standards developed by the IEEE 802.3 committee.

Hub: A LAN connection device. A hub acts as a multiport repeater, to which multiple stations attach, each on a point-to-point link. A transmission on any one link from a station to the hub is repeated on all other links.

Layer 2 switch: A LAN connection device that operates somewhat like a multiport bridge. Typically, a LAN switch offers full-duplex operation so that multiple stations may be transmitting at one time.

Local area network (LAN): A communications network that encompasses a small area, typically a single building or cluster of buildings, used to connect various data processing devices, including PCs, workstations, and servers.

Media access control (MAC): The method of determining which device has access to the transmission medium at any time.

INTRODUCTION

Local area networks (LANs) have evolved since the late 1970s to become central elements in corporate networks around the world. Many of today's LANs are based upon one or more of the network technologies that originated as one of the early standards developed within the Institute of Electrical and Electronic Engineer's (IEEE's) Project 802. The Token Ring Working Group, IEEE 802.5, which produced a family of token ring standards throughout the 1980s and 1990s, played a central role in the evolution of one highly popular LAN technology, particularly in commercial environments. Both the IEEE 802.5 and the ANSI X3T9.5 FDDI token ring standards were developed through the collaboration of many individuals representing a broad segment of the network industry. These token ring standards were subsequently endorsed as worldwide standards by the International Organization for Standardization (ISO).

BRIEF HISTORY OF RING NETWORKS¹

A token ring network is distinguished from other networks by a combination of network topology and an access method that allows hundreds of devices to reliably share the total available bandwidth. Token ring and the predecessor networks were based on evolving time division multiple access (TDMA) schemes where a common media was used for both transmit and receive operations by tens or hundred of devices. Researchers continued their quest for the ideal protocol that was both efficient and reliable. The loop systems of the 1970s were important precursors to ring systems. In both systems, network nodes are interconnected in a serial fashion forming a

closed loop (or ring) on which encoded digital information flows in one direction. Loop and ring systems can be distinguished by their respective access control schemes. Loops operate in a master/slave fashion in which access to the media is governed by a single master control node via the periodic issuance of a special control message known as the poll. Upon receipt of the poll, selected network nodes are permitted to send data to the master control node. In contrast, all nodes on a ring system are peers and autonomously determine when to transmit, based on the state of the ring. Early token ring prototypes also demonstrated that data transmission rates of 1 megabit per second (Mbps) and greater were achievable, representing a significant advancement over the 56 kilobits per second (kbps) link rates that were prevalent at the time.

One of the first accounts of a ring-based communication system was presented by Farmer and Newhall (1963); other significant ring networks include the Distributed Computing System (DCS) (Farber, Feldman, Heinrich, Hopwood, Larson, Loomis, and Rowe, 1973), the Pierce ring (Pierce, 1972), the ring built at MIT (Saltzer and Pogran, 1979), the Cambridge ring (Hopper, 1977), and the ring network at the IBM Zurich Research Laboratory (Bux, Closs, Janson, Kümmerle, Müller, and Rothauser, 1981).

Both the Pierce ring and the Cambridge ring utilized a slotted-ring technique where multiple fixed-length data slots continuously circulate around the ring. Any node can place a data packet (or a packet fragment) in one of the empty slots, along with the appropriate address information. Each node examines the address information and copies those slot contents destined to that node.

In a second type of ring system, the buffer or register insertion ring, contention between data ready to be transmitted by a node and the data stream flowing on the ring is resolved by allowing the transmitting node to dynamically insert sufficient buffer space into the ring to avoid loss of data (Hafner, Nenadal, and Tschanz, 1974; Reames and Liu, 1975).

¹This paper is an updated revision of a previously published paper by Werner Bux and Norman Strole. 1999. "Token Ring Networks," *Wiley Encyclopedia of Electrical and Electronics Engineering*, Vol 22, edited by John G. Webster, pp. 274–80. Reprinted with permission of John Wiley & Sons, Inc.

A third scheme known as token-access control was first implemented in the DCS and the Massachusetts Institute of Technology (MIT) rings, and was the basis for the ring system built at the IBM Zurich Research Laboratory. It also underlies two important LAN standards, the IEEE 802.5 Token Ring (ISO/IEC 8802-5, 1998) and the American National Standards Institute (ANSI) X3T9.5 fiber distributed data interface (FDDI) (ISO 9314-1,2 & 3, 1989/90). In a token ring, access to the transmission medium is controlled by passing a unique digital signal, the permission token, around the ring. Each time the ring is initialized, a designated node generates a token that travels around the ring until a node with data to transmit captures the token and transmits its data. At the end of its transmission, the node passes the access opportunity to the next node downstream by generating a new token.

Standardization has played an important role in the evolution of the various LAN technologies. LAN standards have been developed primarily by the IEEE, the European Computer Manufacturers Association (ECMA), and ANSI. Token ring standardization was pursued by the IEEE 802.5 committee, which produced its first standard in 1984. ANSI ratified it as an American National Standard in 1985 and forwarded it to ISO in 1985, which approved it as an International Standard (IS) in 1986. In Europe, ECMA issued its first token ring standard, ECMA-89, in 1982.

The IEEE 802.5 Token Ring Standard was to a considerable extent based on contributions from IBM Corporation, which in the late 1970s had investigated various LAN techniques in its Zurich Research Laboratory. The token ring topology and protocol was found to be particularly applicable to commercial applications, with a number of advantages over other LANs. Performance studies showed that the token protocol was more efficient as the network load increased and that a token ring was not subject to the same distance constraints as collision-based access protocols (Bux, 1981). IBM's research also represented an advancement beyond earlier ring concepts in an effort to define a system architecture that was reliable, easily deployed, and relatively simple to recover from errors or faults. One important innovation was the introduction of a central wiring concentrator unit and the star-ring topology. Robustness of the token ring was improved through the concept of a backup ring path that would permit self-healing when a break in the primary ring occurred. A method to ensure that there was always a token on the ring was introduced with the development of the token monitor concept. The design of a priority access mechanism provided the basis needed to support real-time applications such as voice (Bux et al., 1981) and (Bux, Closs, Kümmerle, Keller, and Müller, 1983).

The first network adapter and concentrator products to support the IEEE standard were shipped by IBM and Texas Instruments in 1985. Several other companies joined them to provide a wide range of token ring products throughout the 1990s. IEEE standard-based token ring deployment declined, and in many instances, was replaced by higher-speed 100-Mbps and 1-Gbps switched Ethernet products in the early 2000s. However, the original IBM Cabling System remains in use as the transmission

media for these 100-Mbps and 1-Gbps systems over 20 years after it was initially deployed for 4-Mbps LANs.

IEEE 802.5 Standards Evolution

IBM's technical contribution to the IEEE Project 802 committee in March, 1982 formed the basis for the initial IEEE 802.5 Token Ring Standard. This standard incorporates both the Physical (PHY) and Media Access Control (MAC) layers, which are Layers 1 and 2 of the Open Systems Interconnection (OSI) reference model (Strole, 1983). Token ring was initially standardized at the PHY layer as a 4-Mbps data transmit rate over 150-ohm shielded twisted pair (STP) cables known as the IBM Cabling System. Shortly after the issuance of that standard, subsequent releases expanded the cabling options to include 100 ohm unshielded twisted pair (UTP) cabling (i.e., telephone grade wire), and optical fiber. These were followed by standards for 16-Mbps token ring, first on 150-ohm STP cabling and optical fiber and later on 100-ohm UTP. Support of the 100 ohm UTP cabling required the introduction of active concentrators. The migration from a shared-ring to a dedicated, switched link per station, known as dedicated token ring (DTR), provided a transition path for 16-Mbps operation as well as for 100-Mbps token ring operation. With each of these changes, the frame format remained the same so that any token ring formatted frame could be easily and economically bridged between token ring segments operating at different speeds.

TOKEN RING TECHNOLOGY

Basic Protocol

Information on a token ring is transferred sequentially from one node to the next. The token is a control signal composed of a unique signaling sequence that any node may capture (Figure 1a). The node having control of the token, and thus sole access to the medium, transmits information onto the ring (Node A in Figure 1b). For IEEE 802.5 operation, capturing the token is accomplished by simply modifying a single bit on-the-fly to form a start-of-frame sequence, and then appending appropriate control information, address fields, the user information, frame-check sequence, and a frame-ending delimiter. All other nodes repeat, and thus redrive, each bit received. The addressed destination node copies the information from the ring as it passes (Node C in Figure 1b). After completion of its information transfer and after checking for the correct return of its frame header, the sending node generates a new token which provides other nodes with the opportunity to gain access to the ring (Node A in Figure 1c). The transmitting node keeps the ring open by transmitting idle characters until its complete frame has returned to be removed. The transmit opportunity passes with the token to all other nodes on the ring before a node can seize the token again to send additional data.

The maximum frame size is bounded by the maximum transmit time when a token is captured. The IEEE 802.5 standard defines this time as 9.1 milliseconds (e.g., 0.0091 seconds). Because the number of 8-bit octets transmitted in a fixed time period is dependent upon the data transmit rate, the upper limit becomes 4550 octets at 4 Mbps and

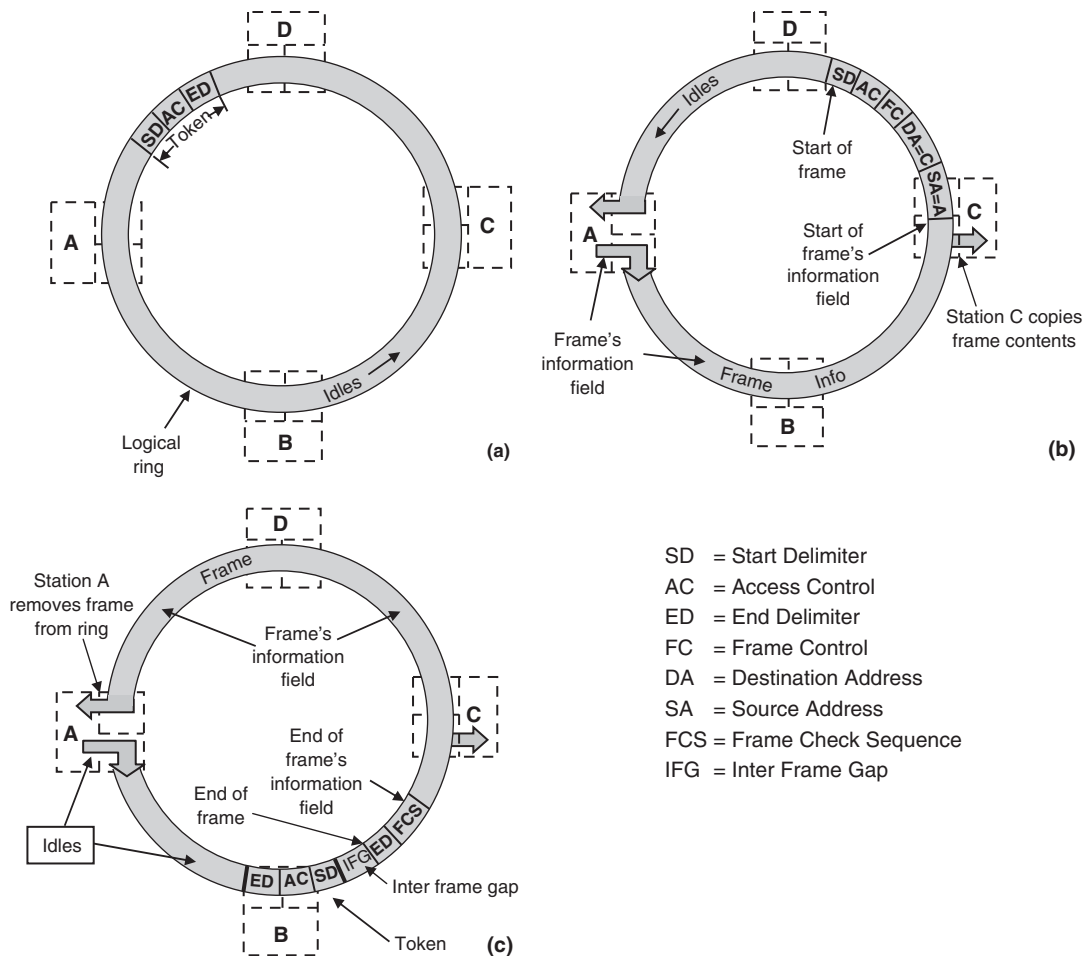

Figure 1: Token protocol overview. Reproduced by permission from James T. Carlo, Robert D. Love, Michael S. Siegel, Kenneth T. Wilson, *Understanding Token Ring Protocols and Standards*, 1998. © 1998 by Artech House, Inc.

18,200 octets at 16 Mbps (Carlo, Love, Siegel, and Wilson, 1998).

An important and unique characteristic of ring networks is that each node becomes an active participant in all ring communications, because each node must forward or re-transmit the data signal to the next downstream node. This fundamental property is reflected in the wiring and transmission techniques that have been chosen for token rings, as described below.

Star Wiring

Because information flows sequentially from node to node around the ring, a failure in a single node can disrupt the operation of the entire ring. This potential problem is addressed by the star-wiring topology in which each node is wired to a so-called wiring concentrator or multistation access unit, although the wiring concentrators are interconnected with point-to-point links (Figure 2). Wiring lobes, consisting of two distinct send and receive signal paths, radiate from the wiring concentrators to the various network interface points, typically wall outlets, in a building. The wall outlets provide physical interfaces to the network to allow fast, reliable, and convenient attachment or relocation of workstations or servers.

The lobes are physically interconnected within the concentrators via electromechanical relays to form a

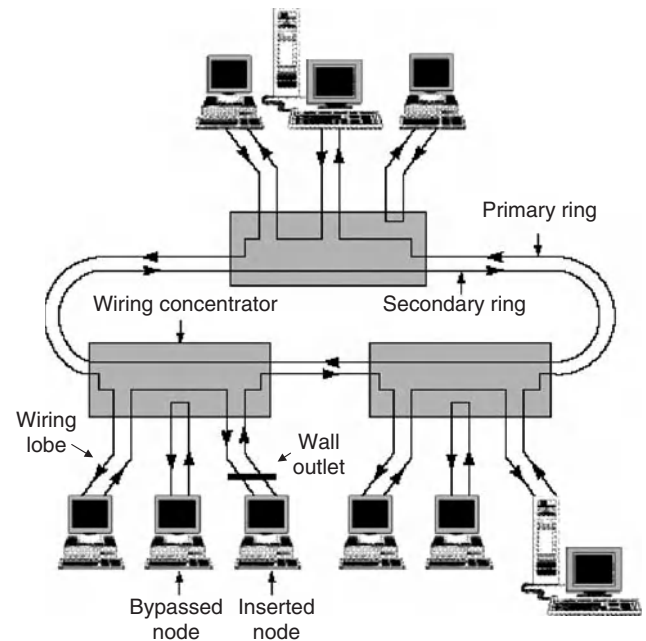

Figure 2: Star-wiring topology with dual ring example. Reproduced by permission from James T. Carlo, Robert D. Love, Michael S. Siegel, Kenneth T. Wilson, *Understanding Token Ring Protocols and Standards*, 1998. © 1998 by Artech House, Inc.

serial link. A lobe is only included in the ring path when the node is active; otherwise the bypass mechanism in the wiring concentrator causes that lobe to be skipped. If the bypass mechanism were positioned at the node itself, the inactive lobe would cause an undesirable increase in the distance between the active nodes on the ring. The wiring concentrators can be completely passive, that is, contain relays but no active elements, such as processing logic or power supplies, and require only enough power from an attached node to activate the relays when a node needs to get inserted into the ring. The concentrator design and interconnect scheme also provides an alternate ring path that can be used to bypass a break or disruption in the primary ring path (Figure 2).

As an alternative to the simple passive wiring concentrators, active concentrators or "hubs" later became very popular among users who required more stringent availability and manageability features. Active concentrators incorporate additional processing capability and contain either one or two complete token ring nodes, that is, they represent addressable entities, which enable them to provide powerful management, security, and reconfiguration functions. Furthermore, active concentrators may be combined with a bridging function to other rings or a high-speed "up-link" to a LAN switch.

When optical fibers are used to interconnect wiring concentrators and the nodes, insertion/removal signaling is accomplished via optical rather than electrical signals. The control information for ring insertion can be carried by special MAC control frames or unused code symbols; an alternative is to use out-of-band signaling with a suitable form of multiplexing. Wiring concentrators need to be active in this case.

Pre-cabling an office area or building with star wiring is practiced for most LAN installations and has a number of additional advantages:

1. It provides centralized points for reconfiguration management.
2. Workstations can easily be moved from one location to another without requiring installation of a new cable.
3. The wiring is segmented at the wiring concentrators rather than being a continuous cable, thus permitting the intermixing of transmission media. For example, twisted-pair wire can be used to interconnect the wiring concentrators and nodes, whereas optical fiber is employed for the transmission links between wiring concentrators.
4. As long as a node is in passive state (i.e., not inserted in the ring), its lobe is wrapped around in the wiring concentrator (Figure 2). This enables the node to perform a self-check before inserting itself into the ring. Should an active node detect a fault within either its own components or its wiring lobe, it can remove itself from the ring.

Transmission Media

When token ring was initially under development in the early 1980s, it was thought that telephone-grade unshielded twisted pair cabling was incapable of carrying

high speed (4 Mbps) signals for sufficient distances to be practical for commercial LAN applications. Therefore, a specially designed STP cabling was simultaneously developed by IBM. In 1984 the IBM Cabling System using 150 ohm STP copper media for deployment in a star topology was introduced. Commercial customers embraced the star-wired topology but were unsatisfied with the large diameter of the 150 ohm cabling and subsequent cable expense. In that same time frame, the telephony industry was looking at ways to use thinner telephone wiring for high-speed data transmission and realized that to do so telephone wire would have to be substantially improved. Those improvements had not reached the market when the first token ring products became available in 1985. At that time complex wiring rules were published for robust operation of the token ring protocol over large networks spanning multiple wiring closets and containing up to 260 devices (Carlo et al., 1998, 64-9). As a result of customer demand to use existing telephone wires, alternate rules were also published for more modest networks of up to 100 nodes, all cabled to the same wiring closet (Carlo et al, 1998). Minimum requirements were placed on the telephone wire, which was dubbed "Type 3 media." During this time frame the telephony industry was also developing and standardizing improved telephone wiring and connectors for the express purpose of carrying high-speed LAN data for both token ring and Ethernet applications, first in North America under the auspices of TIA, and later internationally, under JTC/1 SC25/WG3. The North American Standard for telecommunication grade cabling was TIA/EIA 568. The first edition of that standard included the 150 ohm cabling of the IBM Cabling System, and a more rigorous standard for data grade telephone wire called Category 3 cabling. Later editions of that standard specified a Category 5 (and later Category 5e) telephone wiring, which was crucial for supporting token ring's next generation of hardware operating at 16 Mbps and later at 100 Mbps. The international standard, IS11801, specified the 150-ohm IBM data grade cable, as well as both Category 3 and Category 5 twisted pair cabling. Category 5 (and later Category 5e) cabling was more advanced, with better transmission characteristics and became the de facto twisted pair data cable. As token ring increased its operating speed, first from 4 to 16 Mbps and then to 100 Mbps, the requirement to operate over Category 5 cabling at distances of up to 100 meters had to be addressed. The solution at 16 Mbps was to require the concentrators to be active devices, repeating the signal between each pair of wiring concentrators but not between the nodes themselves. The solution at 100 Mbps was to use a more efficient line coding and to operate in DTR mode where each signal received by the concentrator from any of its attachment ports was regenerated and retransmitted to the next lobe. DTR design required one active device in the concentrator for each end station that attached to it. These topology and signal reclocking changes were required to overcome the signal attenuation that occurs over the copper media as the signal clock rate increases, thus decreasing the maximum distance before the signal must be reclocked.

Although there were two principle choices for cabling from the wiring closet to the active devices in the offices

and within the wiring closet, the requirement to be able to transmit over multi-100 meter lengths between wiring closets and between buildings was addressed with optical fiber transmission media. Although optical fiber media could have been used to attach devices located in offices, it never gained significant market share for that application as a result of attachment and media cost.

Advances in signal processing technology have allowed transmission rates to increase from 100 Mbps to over 1000 Mbps while maintaining a clock rate that allows the 100-meter length to be maintained. Subsequent advances in the copper cable design and digital encoding schemes since the 1990s have resulted in transmission capacities of up to 10 gigabits per second (Gbps) over short distances (up to 15 meters), with the promise of longer distances in the future. Much of this increase in transmission capacity over copper media can be attributed to the advancements in Application Specific Integrated Circuit (ASIC) technology and digital encoding schemes.

Line Coding

The data generated by a node must be encoded for transmission over a ring network. The IEEE 802.5 standard specifies differential Manchester encoding for both the 4- and 16-Mbps token ring transmission rates (Figure 3a). Differential Manchester encoding is characterized by the

transmission of two line signal elements per bit, resulting in a link clock rate that is double the bit transmission rate. In the case of a binary one or zero, a signal element of one polarity is transmitted for one half-bit time, followed by the transmission of a signal element of the opposite polarity. This line coding has two advantages: 1) The resulting signal has no DC component and can readily be inductively coupled, and 2) the mid-bit transition conveys inherent timing information. The ones are different from the zeros at the leading bit boundary; a value of one has no signal transition at the bit boundary, whereas a value of zero does. In decoding the signal, only the presence or absence of the signal transition and not the actual polarity is detected, thus interchanging the two wires of the twisted pair introduces no data errors. A code violation results if no signal transition occurs at the half-bit position. Code violations can be intentionally created to form a unique non-data signal pattern that can be distinguished from normal data (Figure 3b). These so-called J/K signals can be inserted to mark the start or end of a valid data frame. The J/K code violations are used in pairs to maintain the DC balance of the Manchester signaling.

Manchester coding is a very simple and robust technology, but, at the same time, is also very bandwidth inefficient and therefore not suitable for transmission rates significantly higher than 16 Mbps. For example, in FDDI,

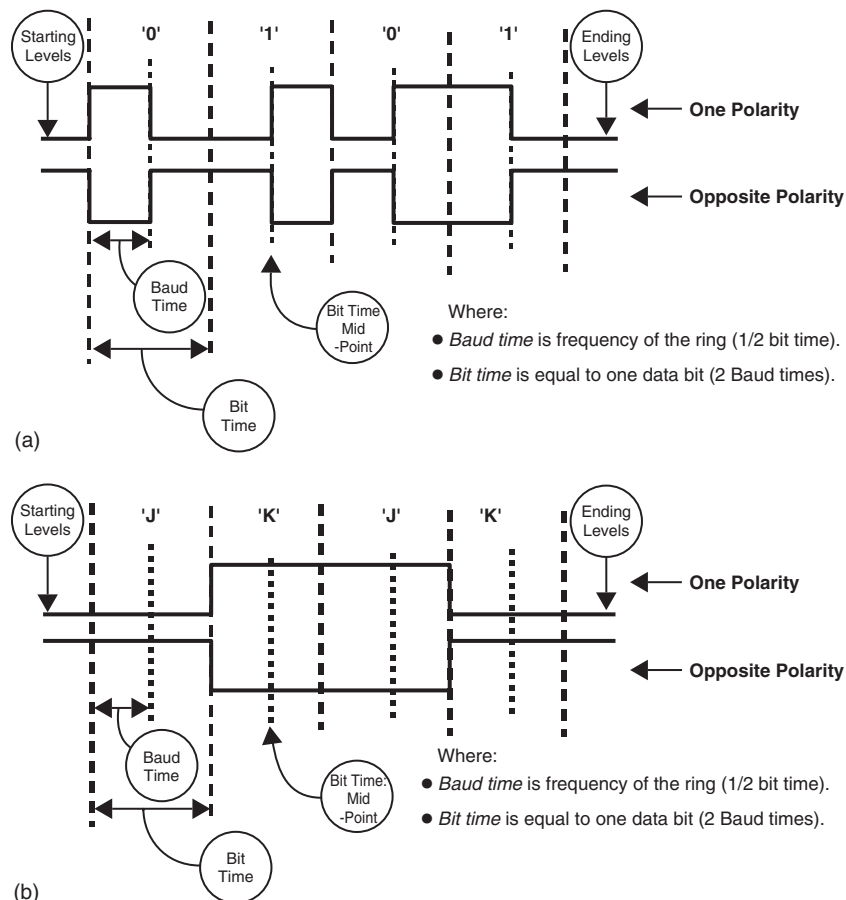

Figure 3: Differential Manchester encoding. Reproduced by permission from James T. Carlo, Robert D. Love, Michael S. Siegel, Kenneth T. Wilson, *Understanding Token Ring Protocols and Standards*, 1998. © 1998 by Artech House, Inc.

information on the medium is transmitted in a 4-out-of-5 group code (4B/5B) with each 5-bit code group, called a symbol, used to represent 4 bits of data. The symbols are transmitted in a Non-Return to Zero Inverted (NRZI) line transmission format (ISO/IEC 9314-3, 1990). NRZI is distinguished from Manchester in that

1. There are no transitions at the half-bit boundary.
2. Transitions occur at the beginning of a binary "1," and
3. No transition occurs at the beginning of a binary "0."
4. The 4B/5B encoding scheme has excess code groups that can be used as nondata symbols to distinguish the start and end of a valid data frame.

Synchronization

Synchronization of the link clocking among stations is a key technical problem in the design of any ring system. Rings built according to the IEEE 802.5 standard employ a centralized clocking technique. In normal operation, one node on the ring is automatically designated as the active monitor during ring initialization. The monitor plays a crucial role in the supervision of the ring, as will be described below. In addition, it provides the ring master clock. All other nodes on the ring are frequency and phase-locked to the monitor. They extract timing from the received data by means of a phase-locked loop while redriving the digital signal to reach the next node. Each port of an active concentrator can also reclock and redrive the signal as well.

Although the mean transmission rate on the ring is controlled by the active monitor node, segments of the ring can, instantaneously, operate at rates slightly different from the frequency of the master oscillator. The cumulative effect of such rate variations are sufficient to cause variations of a few bits in the latency of a ring. Unless the latency of the ring remains constant, bits would have to be either dropped or added. To maintain a constant ring latency, an elastic buffer is provided in the monitor. If the received signal at the active monitor node is slightly faster than the master oscillator, the buffer will fill up to avoid dropping bits. If the received signal is slow, the buffer will be emptied to avoid adding bits to the repeated bit stream. Detailed discussion and analysis of this clocking scheme are given in (Müller, Keller, and Meyr, 1983) and (Carlo et al., 1998).

A major advantage of the centralized clocking approach is that it minimizes the total latency of the ring and thus allows use of the IEEE 802.5 protocol, which, for optimum performance, requires the ring latency to be small. An alternative synchronization technique that introduces greater latency but is easier to implement at high transmission rates is employed in FDDI, where information is transmitted between nodes asynchronously; that is, each node uses its own autonomous clock source to transmit or repeat information on the ring (ISO 9314-1, 1989). This type of operation requires the use of an elastic buffer at every node. Information is clocked into the buffer at the clock rate recovered from the incoming bit stream, but is clocked out of the buffer at the autonomous fixed clock rate of the node. A preamble that precedes

each frame enables the buffer to be reset to its midpoint prior to frame reception. The reset operation increases, or decreases, the length of the preamble. For the IEEE 802.5 100-Mbps token ring operation, the issue of ring latency was sidestepped by defining only a switched token ring operation with one active repeater node in the wiring closet for each attached station. With this configuration, the attached station and its active repeater form a two-station ring. The active repeater acts like a bridge sending information onto this two-station ring, and broadcasting information received from the attached station to the other direct-attached stations.

TOKEN RING ACCESS PROTOCOL, MONITORING, AND RECOVERY

Data Frame Format

Figure 4 shows the token format and the general format for transmitting information on the ring, called a frame. A token contains only the access control (AC) subfield and the starting and ending delimiters (Figure 4a). The one-byte AC field includes a one-bit token (T) indicator that indicates whether this is a token (0) or a frame (1). A token priority mode that uses the priority reservation indicators provides different priority levels of access to the ring (see below). The monitor (M) bit is used in connection with the token monitor function to maintain the validity of the token.

The "data" portion of the frame is variable in length and contains the information that the sender is transferring to the receiver. The information (INFO) field is preceded by a header, which contains several subfields (Figure 4b). The first is a starting delimiter (SD) that identifies the start of the frame. The starting delimiter is a unique signal pattern that includes pairs of code violations of the differential Manchester encoding scheme as described earlier (Figure 3b). Next, the AC subfield, with the token bit (T) set to 1, is defined for controlling transmit access to the shared media as described above. The frame control (FC) subfield contains a two-bit frame format (FF) and a three-bit frame priority subfield. The frame format enables the receiving node to determine if the information within the data field of the frame contains media access control (MAC) information (FF = 00) or user data (FF = 01). MAC frames may optionally include frame status information within the control indicator subfield. Finally, the header includes the source address (SA) of the node that originated the information and the destination address (DA) of the node (or nodes) destined to receive the information. Both address fields contain six bytes, with the first two bits of the DA designating that the address is intended for multiple destination nodes (group bit) or that the address has been assigned by the user (local administered address bit). Use of the routing information field (RIF) will be described in the section on multiring networks.

The information field is followed by a trailer that is composed of three subfields. The first portion of the trailer contains a 4-byte frame check sequence (FCS) that is calculated by the source node and used by downstream nodes for detecting bit errors that may occur within the frame

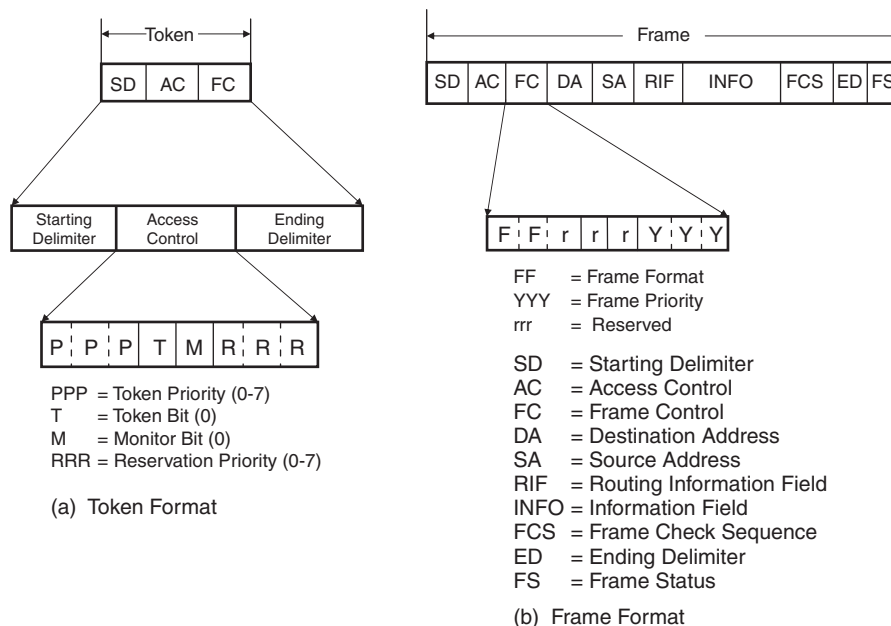

Figure 4: Token and frame formats. Reproduced by permission from James T. Carlo, Robert D. Love, Michael S. Siegel, Kenneth T. Wilson, *Understanding Token Ring Protocols and Standards*, 1998. © 1998 by Artech House, Inc.

during transmission bounded by the FC subfield and the last bit of the information field. Next, an ending delimiter (ED) is provided to identify the end of the frame. This delimiter also contains a unique, although slightly different, bit combination along with pairs of code violations as were found in the starting delimiter. The last bit of the ending delimiter is designated as the error-detected indicator (EDI). This indicator will always be zero during error-free ring operation. The ending delimiter is followed by a one-byte frame status (FS) field. The FS field contains bits that can be modified while the frame is traversing the ring by nodes that match the destination address and/or copy the frame. The FS field is therefore not included in the calculation of the FCS character. For this reason, these bits are defined as pairs to avoid erroneous conditions as a result of single-bit errors on the wire.

Priority Protocol

In some applications, it may be necessary for selected nodes to gain priority access to the ring. A priority scheme was designed specifically for the token ring protocol that was initially one of the distinguishing features versus other access control schemes. The priority (PPP) and reservation (RRR) indicators in the access control (AC) field are used to facilitate this access scheme (Figure 4b). Various nodes may be assigned priority levels for gaining access to the ring, with the lowest priority being “000” and the highest being “111.” This allows up to eight protocol levels to be defined. A selected node can seize any token that has a priority setting (bits 0-3) equal to or lower than its assigned priority. The requesting node can set its priority request in the AC reservation field (bits 5-7) of a frame as it is being repeated if that node’s priority is higher than any current reservation request. The current transmitting node must examine the reservation request in the returning frame and release the next token with the new

priority indication (bits 0-3), but retain the previous priority level within its MAC state information for later release. A requesting node uses the priority token and releases the new token at the same priority so that any other nodes assigned that priority can also have an opportunity to transmit. When the node that originally released the priority token recognizes a token at that priority, it then releases a new token at the level that was interrupted by the original request. Thus, the lower priority token resumes circulation at the point of interruption.

In 1995, the IEEE 802.5 standard committee published a set of guidelines for the use of previously reserved priority levels 5 and 6. Priority 5 is recommended for delay sensitive, high-bandwidth data streams such as video applications. Priority 6 is recommended for delay sensitive, low-bandwidth data streams, such as interactive voice communication. Priority 7 is reserved for ring management and error recovery frames. Priority 4 is generally recognized for bridge access.

Token Protocol Performance Issues

From a performance point of view, token rings have two distinct advantages over other access protocols:

1. As a result of the cyclic operation (also sometimes referred to as “round robin”) enforced by the rotating token, all users of the ring are serviced in a perfectly fair fashion within a given priority class. The priority mechanism, however, may be used to give a subset of the users preferential service as described above.
2. As a result of its deterministic behavior, the token protocol scales better with respect to network latency than random access protocols such as CSMA/CD.

However, the original IEEE 802.5 protocol is not totally insensitive to ring latency because it requires that idle

characters be inserted by a transmitting node until it has recognized its source address in the header of the returning frame. This leads to improved error robustness of the operation and is required for a higher priority token to be released, but results in decreased efficiency as the physical ring length, number of active nodes, and/or the ring speed increase.

Ring protocol efficiency can be maximized at very high speeds and/or long ring lengths if nodes release the token immediately after finishing frame transmission. In 1987, the IEEE 802.5 standard was enhanced by an early token release (ETR) option that allows a transmitting node to release a new token as soon as it has completed frame transmission, whether or not the frame header has returned to that node. This enhancement was necessary to allow the support of 16-Mbps operation over large campus networks. One impact of ETR is that priority reservations applied to "short" frames are lost until the circulation of a subsequent frame that exceeds the ring length. This trade-off was shown to be acceptable for typical campus-wide 16-Mbps rings. A detailed discussion of token ring performance issues can be found in (Bux, 1989).

Ring Monitor Function

In token ring networks, error detection and recovery mechanisms are provided to restore network operation in the event that transmission errors or medium transients, for example, those resulting from node insertion or removal, cause the ring to deviate from normal operation. The IEEE 802.5 token rings utilize a network monitoring function that is performed in a specific token monitor node with backup capability in all other nodes attached to the ring. The monitoring function is based on the scheme developed by the IBM research team in Zurich (Bux Closs, Kümmerle, Keller, and Müller, 1983). Through an arbitration process, the nodes on the ring select one node to be the active monitor. As described above, this is also the node providing the master clock for the ring. The remaining nodes function as standby monitors. The active monitor keeps watch over the health of ring and token, activating recovery procedures when necessary.

Ring errors can be quickly isolated to a specific ring segment if an accurate map of the ring stations is maintained. Periodically, the active monitor will issue a broadcast frame called an active monitor present (AMP) frame. The first active node downstream from the monitor node will set the address recognized indicator (ARI) bits in the FS subfield and save the source address. Other nodes on the ring will ignore this particular broadcast frame when the ARI bits are set. The node that received the AMP frame will then issue a standby monitor present (SMP) frame containing its own source address whenever a token is observed. This frame is recognized and copied by the next downstream active node. This process continues around the ring until the active monitor receives the SMP frame without the address-recognized flag set. At that time, each node will have the specific address of the adjacent node immediately upstream. This is known as the nearest active upstream neighbor (NAUN). The

NAUN information is transmitted with all beacon frames and soft error report frames, thereby allowing a network management node to log the logical location of the fault. The AMP and SMP frames are transmitted at the highest ring priority to insure that the process completes in the least amount of time, even during periods of peak ring utilization.

Ring Fault Detection and Isolation

The topological structure of a star-ring configuration, in conjunction with the token-access control protocol, permitted the development of additional protocols for rapid detection and isolation of network faults (Strole, 1983) and (Carlo et al., 1998). The unidirectional propagation of information (electrical signals and data frames) from node to node provides a basis for detecting certain types of network faults. Network faults can be categorized into two types: hard faults and soft faults.

A hard fault occurs when there is a complete break in the ring wiring between two adjacent nodes or wiring concentrators or a failure in the transmitter or receiver elements of a node. A node that detects loss of signal at its receiver will begin transmitting a unique series of contiguous MAC frames. Such a transmit state is called "beaconing." A hard fault may initially cause more than one node to enter the beacon state, but eventually all nodes but the one immediately adjacent to and downstream of the fault will exit the beacon state as they begin receiving beacon frames from their upstream neighbors. Thus, the location of the fault will be isolated to the particular ring segment and the last known NAUN that is immediately upstream from the node that is transmitting beacon type frames.

A soft fault is characterized by a high frame error rate, usually caused by a degradation in the electrical signal or environmental electromagnetic interference. The frame check sequence (FCS) of all frames is calculated and verified by all intermediate nodes as the frames are repeated. The first node on the ring that detects an FCS error sets the error detected indicator (EDI) in the ending delimiter field as an indication to all other nodes that the error has been logged. If a predetermined threshold of FCS errors is reached over a given time interval, an indication of the condition can be reported to a network management application. The location of the soft fault can be readily determined from the information in the error report message and isolated to the ring segment immediately upstream of the reporting node.

Once the location of a fault (hard or soft) has been determined, several options are available for eliminating the faulty segment(s) from the ring so that normal operation can resume. The wiring concentrators provide concentration points for bypassing such faults, as was discussed earlier with lobe bypass. Also, alternate backup links are normally available between the wiring concentrators in parallel with the principal links. If a fault occurs in the ring segment between two wiring concentrators or if a concentrator failure occurs, wrapping of the principal ring to the alternate ring within the two wiring concentrators on either side of the fault will restore the physical path of the ring (Figure 5). This wrapping

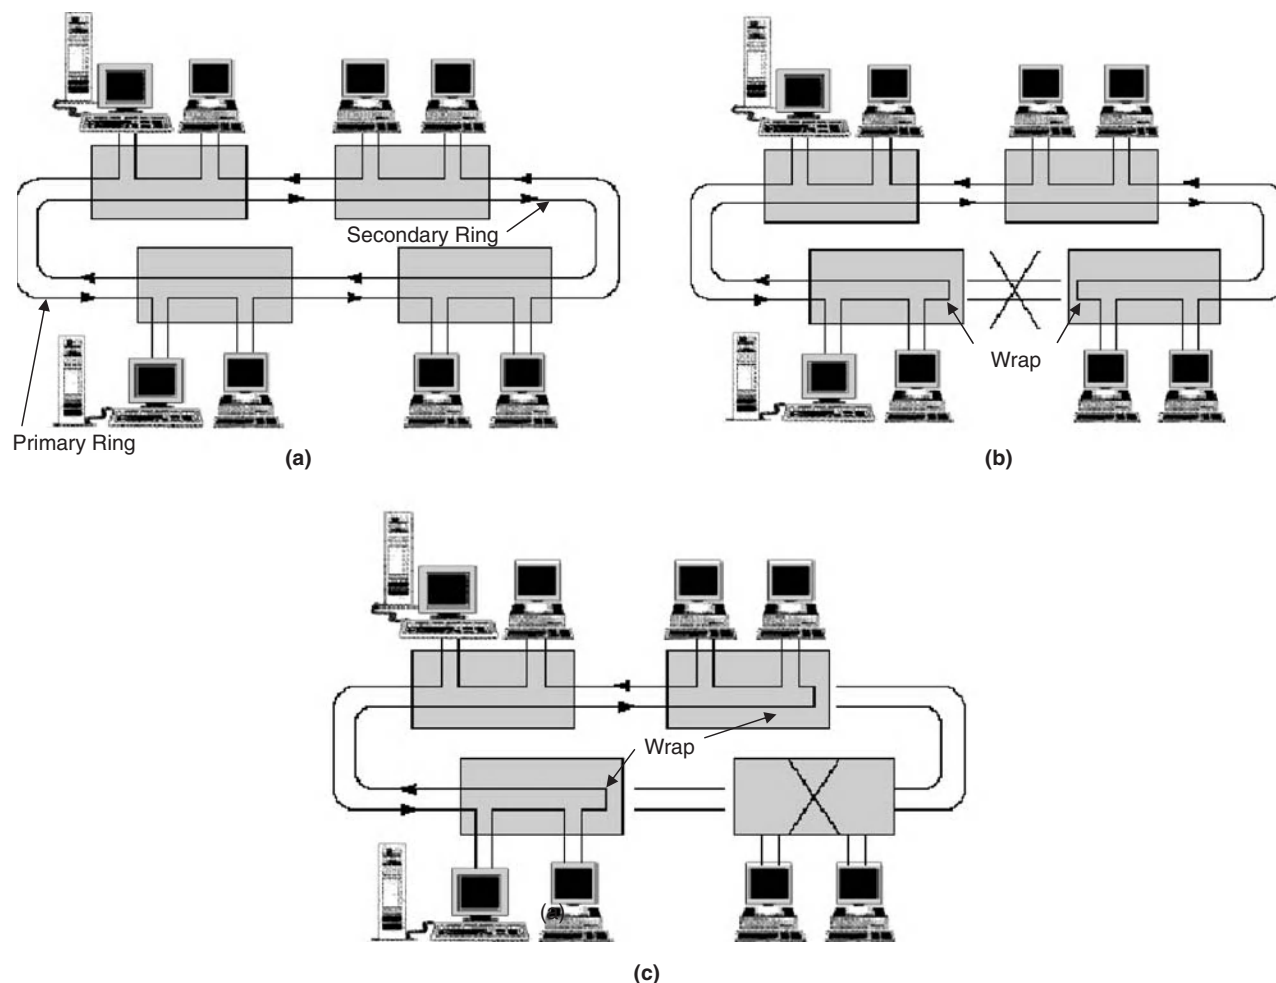

Figure 5: Fault detection and isolation with wiring concentrators. Reproduced by permission from James T. Carlo, Robert D. Love, Michael S. Siegel, Kenneth T. Wilson, *Understanding Token Ring Protocols and Standards*, 1998. © 1998 by Artech House, Inc.

function, like the lobe bypass function, is automatic in active concentrators. Figure 5 shows four wiring concentrators as they would be configured with both a principal and an alternate ring. The signals on the alternate ring are propagated in the direction opposite to those on the principal ring, thus maintaining the logical order of the nodes on the ring.

MULTIRING NETWORKS

Multiple rings are required in a campus or building LAN when the aggregate data transfer requirements or total number of stations exceed the capacity of a single ring or when a large number of attached nodes are spread over a broad area (Strole, 1983). Two rings can be linked together by a high-speed interconnect mechanism known as a bridge (Figure 6). A bridge is capable of providing a logical forwarding of frames between the rings based on the SA, DA, and/or RIF inserted by the source node. An additional capability of the bridge is to perform transmission speed changes from one ring to another. Each ring retains its individual identity and token mechanism, and could therefore stand alone in the event the bridge or another ring was to be disrupted. The bridge interface to a ring is the same as any other node, except that it must

recognize and copy frames with a destination address or RIF subfield for one of the other rings within the network. Also, several frames may be temporarily buffered in the bridge while awaiting transfer to the next ring. The local network can be further expanded to meet larger data capacity requirements by interconnecting multiple bridges, resulting in a hierarchical network in which multiple rings are interconnected via bridges and multiple bridges are interconnected via a separate high-speed link known as a backbone (Figure 6). The backbone itself may be a high-speed ring, such as FDDI, or it may be another network type, such as an asynchronous transfer mode (ATM) network.

Most token ring and FDDI network devices support a MAC-level bridging scheme known as source route bridging (SRB). With this scheme, intermediate bridges, switches, or routers and the associated ring segments that form the path between a source and destination node are uniquely and explicitly identified within the RIF within the frame header (Figure 4b). The RIF is created via a discovery protocol at the beginning of a session that allows the source node to designate a unique path to the destination node, enumerated as a sequence of bridge and ring segment IDs (Carlo et al., 1998). This scheme simplifies the bridge processing that is required at each intermediate device, whereas also

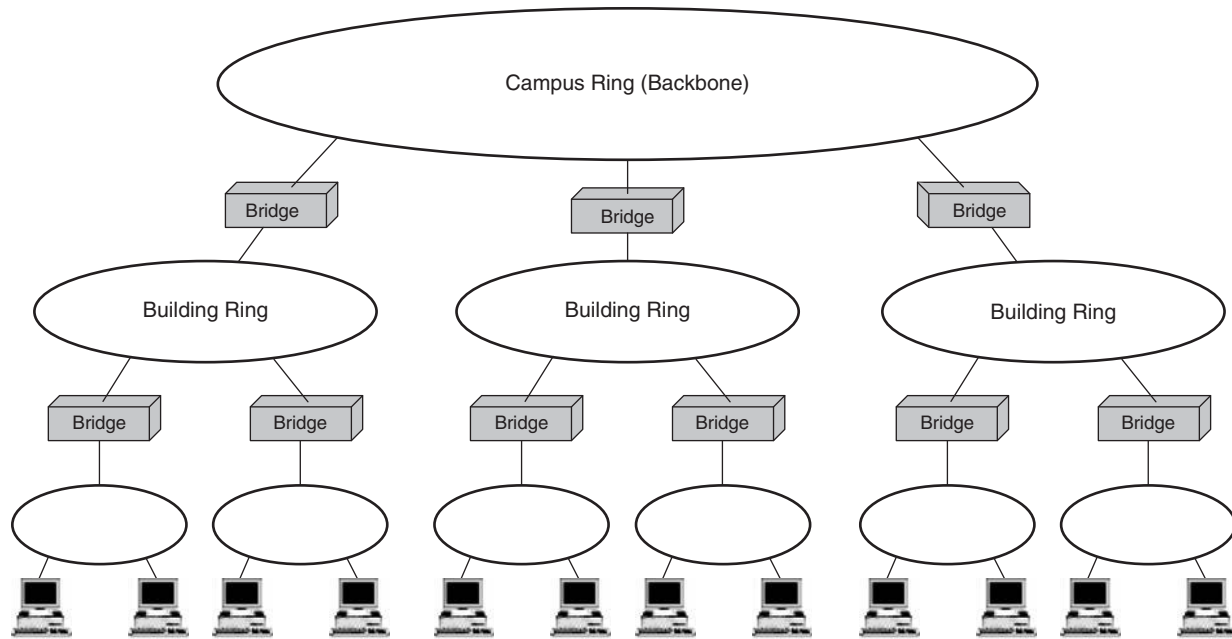

Figure 6: Multiring network topology. Reproduced by permission from James T. Carlo, Robert D. Love, Michael S. Siegel, Kenneth T. Wilson, *Understanding Token Ring Protocols and Standards*, 1998. © 1998 by Artech House, Inc.

providing a mechanism that allows multiple active data paths between two points of the network.

The IEEE 802.1 committee developed standards for LAN bridging. This committee developed an alternate scheme, known as transparent bridging (TB) that required the bridge devices to create and maintain bridge tables to determine which frames to forward (or drop). This scheme was more applicable to the existing IEEE 802.3 Ethernet standard-based products, without requiring changes to the existing adapter hardware and could also be applied to token rings as well. The IEEE 802.1 bridge standard incorporated the criteria for a combination TB/SRB bridge a few years later.

Traditional bridged networks were gradually replaced by switched networks beginning in 1995 (Christensen, Haas, Noel, and Strole, 1995). Fewer nodes per ring segment allow individual nodes access to more of the bandwidth. Dedicated switched links allow one node to use all of the available bandwidth without contention with other nodes.

DEDICATED (“SWITCHED”) TOKEN RINGS

As long as a token ring is operated as a shared medium, the total transmission capacity available to all users can obviously not exceed the ring’s transmission rate. FDDI extended token ring speed to 100 Mbps by using a different token-based media access protocol and different frame format in a separate standard effort that was completed in the late 1980s (ISO 9314-1,2 & 3, 1989/90). The IEEE 802.5 protocol could have been extended to 100 Mbps, but this was not considered to be a commercially viable option with the completion of the FDDI standard.

Overcoming the limitations of a shared-media protocol required the introduction of a high-speed switching function which became technically and economically

possible in the early 1990s with the advancement of ASIC technology. In 1993, the IEEE 802.5 standard committee began looking at options to extend the token ring standard to meet the demand for additional bandwidth. As a result, the DTR standard was completed in 1997. DTR increased the number of ring segments with the introduction of the DTR concentrator by allowing a ring segment to contain one or more stations supported by one active node in the wiring concentrator and introduced the concept of full-duplex operation for directly attached stations (Carlo et al., 1998).

One catalyst for the DTR effort was to leverage the beacon transmit mode that was already present in the hardware design of millions of token ring adapters. In this mode, the node adapter is simultaneously transmitting the beacon frame and receiving frames on the inbound side in order to determine if it is the station nearest to the fault. The existing token ring adapter firmware was modified to create the new full-duplex mode defined by the DTR standard, thus allowing existing adapters to migrate to the new mode with a firmware update combined with the introduction of a multiport token ring packet switch to replace the classic wiring concentrator. DTR also allowed a node to be the only station on a ring shared with the DTR port as the other station. In this case, no change to the station interface is required. The DTR standard and technology was expanded in 1998 to enable 100-Mbps token ring to use Category 5 data cabling, which had become standard in many commercial businesses.

With DTR, a token ring node is allocated the full bandwidth via a dedicated segment between the node and the DTR concentrator (Figure 7) (Carlo et al., 1998). A new mode, full-duplex operation, is also supported. With the full-duplex mode, the token is no longer required. Instead, two dedicated parallel paths are established between the two nodes. For 100-Mbps token ring, up to 200 Mbps of data transfer (100 transmit and 100 receive) can be achieved per link. For 16-Mbps operation, up to 32 Mbps

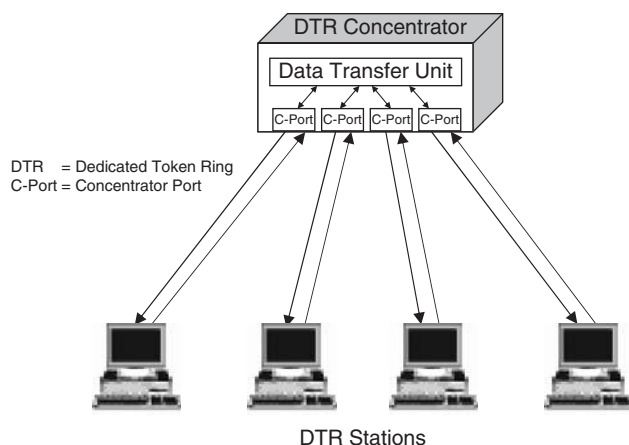

Figure 7: Dedicated token ring example. Reproduced by permission from James T. Carlo, Robert D. Love, Michael S. Siegel, Kenneth T. Wilson, *Understanding Token Ring Protocols and Standards*, 1998. © 1998 by Artech House, Inc.

of data transfer (16 transmit, 16 receive) can be achieved per link. Data frames are forwarded among the dedicated segments by a high-speed data transfer unit within a DTR (Figure 7) or a packet switch (Christensen et al., 1995). For commercial applications, the token ring switch utilizes the existing RIF within the frame header to accelerate the packet forwarding. The effective aggregate bandwidth of the DTR system is determined by the switch capacity rather than the clock speed of the shared media, thus providing much greater bandwidth than the shared-media configuration. Devices attached to a dedicated link have access to the full-duplex bandwidth, thereby providing significantly more application growth potential than with a shared-media access control scheme.

FDDI TOKEN PROTOCOL

A discussion of token ring would not be complete without a more detailed discussion of the FDDI token protocol, which is significantly different from the IEEE 802.5 operation in several fundamental areas (Ross, 1986). Unlike the IEEE 802.5 standard, FDDI defines two classes of data traffic, synchronous and asynchronous (ISO 9314-2, 1989). The synchronous class is applicable to traffic that requires regular intervals between consecutive frame transmissions, such as real-time voice or video for example. Synchronous traffic is given the highest priority and the protocol is designed to guarantee frames of this class a transmit opportunity on each revolution of the token within predetermined bounds on the transmit intervals. Stations requiring synchronous access are assigned reserved bandwidth in advance via a distributed control scheme. Asynchronous frames have up to eight priority levels or thresholds but with no guaranteed access. The protocol allocates asynchronous bandwidth based upon the priority after synchronous demand has been satisfied.

FDDI Token Timers and Operation

Unlike the IEEE 802.5 protocol, control of the FDDI ring under normal operation is decentralized; that is, there is no master station. The algorithm that each station

executes allocates use of the ring based on a fixed value that is the same for all MAC entities on the ring, and on the contents of two timers present in every MAC (ISO 9314-2, 1989). The fixed value is the target token rotation time (TTRT), and the timers are the token rotation timer (TRT) and the token hold timer (THT).

As the network load increases, the TTRT defines the average time for the token to complete one rotation around the ring which, in turn, determines the response time that the network's users need for their synchronous traffic. The stations determine the value for TTRT during ring initialization. The FDDI protocol guarantees that the maximum token wait time for any station on the ring will never exceed 2 times the TTRT value.

One of the timers present in every station's MAC entity is the TRT. In conjunction with a counter called *Late_Ct* (the "late counter"), it indicates the amount of time that has elapsed since the station last received a token. By examining its TRT and *Late_Ct*, a station knows whether the token is taking more or less than the TTRT to complete a rotation. Stations can transmit asynchronous traffic only if the token is received when the *Late_Ct* is zero.

The *Late_Ct* is set to zero by the MAC each time the token is received and the TRT is initialized to the TTRT value each time the token is received early. TRT is a decrementing counter that measures the time required for the token to circulate around the ring. If the TRT expires before the token returns, the *Late_Ct* is incremented and TRT is reset to TTRT and continues to decrement. A late token, or one that arrives when *Late_Ct* = 1, does not reset the TRT, but allows it to continue decrementing, thus carrying forward the lateness of the current token rotation into the next token rotation time. This may restrict a station's ability to transmit asynchronous data frames for multiple successive token rotations. If the TRT expires again while *Late_Ct* = 1, an error condition recovery procedure is initiated by that station.

The second timer used in bandwidth allocation is the THT. Each THT indicates the amount of time that the MAC may use for asynchronous frame transmission. The value of THT for each station will vary from one token revolution to the next, depending upon the network load.

A station may use a "late" token only for synchronous transmission, because the token has taken more than TTRT to complete a rotation. However, if *Late_Ct* equals zero when the station receives the token, the station may transmit asynchronous frames as well. In this case, the THT will determine the amount of time the station may transmit asynchronous frames. A station transmits all pending synchronous frames first. The time required for synchronous transmission has already been factored into the TTRT value and is thus not subject to THT limits. THT is initialized as the residual value of the TRT (e.g., as the difference between TTRT and the amount of time that the early token took to rotate). THT is decremented by the MAC only during the transmission of asynchronous frames. A station may transmit multiple asynchronous frames until the THT expires.

The FDDI priority scheme is based on an array of priority threshold values called *T_Pri*. These values indicate the length of time that the station may transmit frames at a given priority. A station can only begin transmitting frames at a given priority if the remaining THT is greater

than the threshold value for that priority. Thus, under elevated ring loads, it is possible that a given station will be allowed to transmit synchronous frames and only a few of the higher priority asynchronous frames, but will then need to wait additional token rotations to transmit the lower priority asynchronous frames. Dykeman and Bux (1988) provide an in-depth analysis of the FDDI token-access and priority schemes.

Additional details regarding FDDI operation can be found in referenced FDDI standard documentation (ISO 9314-1, 2, & 3, 1989/90).

LAN EVOLUTION

The full-duplex, star configuration continued to evolve from the early 1990s, but the basic principals remained the same. The current generation of LAN switches provides in excess of 100-Gbps internal switch capacity, with the Ethernet packet format being the most widely deployed. These advances are enabled by high-speed ASIC switch technology that allows high-density 1-Gbps and 10-Gbps ports on a single chip. Fiber media is also more pervasive now than in the past and the fiber connector technology has improved significantly. As pointed out in the Transmission Media section, dedicated link speeds of 1 and 10 Gbps are possible today on high-quality copper media as well.

CONCLUSION

This chapter provides both a historical perspective and in-depth technical review of the IEEE and ANSI token ring LAN protocols that emerged in the 1980s. Interested readers are encouraged to refer to (Carlo et al., 1998) as the most comprehensive source on the IEEE 802.5 token ring that is still available today.

GLOSSARY

ANSI: American National Standards Institute, sponsor of the FDDI X3T9.5 standard committee (www.ansi.org).

Bridge: An intermediate device that links two or more network segments together, usually forwarding only those data frames one from link to the other that are required for nodes on the separate links to communicate.

Code violation: A representation of a nondata bit (neither 1 nor 0) in the differential Manchester encoding scheme that can be used to identify the start and/or end of a valid data packet or frame.

Data frame: A variable length packet of information with a predetermined format that usually includes a start of packet delimiter, source and destination addresses, the frame information or payload, and the ending packet delimiter. The frame format varies depending upon the media access protocol (e.g., Token Ring, Ethernet, FDDI).

Data rate: The rate at which data is transmitted on the media, usually in millions of bits (megabits) or billions of bits (gigabits) per second. The effective data rate is usually lower than the actual clock rate on the media.

Dedicated token ring (DTR): An advancement in the token ring operation that allows a single node to utilize all of the link bandwidth without contention with another node.

Early token release: A node releases the token immediately after completing frame transmission and before the beginning of the frame has made a complete pass around the ring. This improves the ring efficiency for very high-speed or extremely long rings by eliminating wasted time.

Fiber distributed data interface (FDDI): A 100-Mbps token ring network standard developed in the mid-1980s by the ANSI X3T9.5 standards body.

Institute of Electrical and Electronics Engineering (IEEE): An affiliation of technical professionals from around the world. The IEEE sponsors international standards development projects, such as the IEEE 802.5 Token Ring Standard (www.ieee.org).

Line coding: The technique used to represent binary information (e.g., 1's and 0's) on the physical media. Differential Manchester and Non-Return To Zero are two example schemes that are used in token ring LANs.

Local area network (LAN): A network that usually spans a confined geographic area, such as an office building or university campus.

Media access control (MAC): The protocol or scheme that is defined for allowing multiple nodes to share access to a common transmission media, usually designed to minimize loss of information and to provide fair access to all of the nodes.

Nearest active upstream neighbor (NAUN): A means to identify the upstream node from a given node. If all NAUNs are known, an accurate ring map can be maintained for problem isolation.

Node: A device or station that is an active element in the network and shares access to the communication media with similar devices or stations.

Physical (PHY): The physical media and interface circuitry that handles the end-to-end signaling via the transmission media.

Token: A predefined, fixed-length packet that circulates on a ring. A node that has data to transmit must hold the token while it is transmitting. This prevents other stations from transmitting at the same time, thus avoiding "data collisions" on the ring.

Token monitor: A designated node on the IEEE 802.5 ring that monitors the health of the token. If the token is lost or damaged, the token monitor must release a new token.

Twisted-pair cable: A copper media used in LAN and telephony applications. Two pairs of copper wires are required for a bi-directional link (transmit and receive). Thus, cables usually have multiple pairs for additional capacity. The copper pairs may be shielded with a foil shield to reduce electromagnetic emissions.

Star wiring: The topology that results when wiring lobes traverse a building from a central wiring concentrator to various locations (offices, work stations, etc.).

Wiring concentrator: A device that allows multiple wiring lobes to terminate at a central point, thus creating

a star configuration as the lobes radiate from the wiring concentrator to the various node locations.

Wiring lobe: The cable link between a node and a wiring concentrator, usually consisting of two pairs of copper media or a single pair of fiber media.

INTRODUCTION

The 1960s saw the advent of digital communications and electromagnetic waves as the primary means for information transmission. There are currently constant demands for increased carrier frequency and larger bandwidth in order to accommodate the increasing volume of processed information (Kolimbiris, 2000). Conventional metallic or coaxial cable often suffer from attenuation as a result of spatial dispersion and heat, noise/interference, and bandwidth constraints, as the energy of higher frequency signals are lost, usually as heat, in traversing the transmission medium where higher frequencies are attenuated as the distance of cable increases (Schneider, 1999). These limitations have sparked the need for new ways to increase the carrier frequencies and the information-carrying bandwidth. As a consequence, a great interest in fiber optics was triggered.

History

The use of light has been an integral part in the development of human communication methods, from early communication signals using light to current optical fiber systems that enable us to cover greater distances. Early systems generally had the constraints of sunlight availability, low information capacity, or distance as in the communication system utilized by sailors who used lamplight to communicate with other ships or the shore in darkness.

Communication systems utilizing light can be traced back to 1880, when Alexander Graham Bell invented the Photophone (Forrest, 1980). The Photophone (see Figure 1) provided the means for Bell to transmit the first wireless telephone message. This was achieved by transmitting sound on a beam of light; the communication process was similar to that of the telephone except that this relied on light instead of electricity as the medium of transmission. The sender utilized sunlight as the light source reflected onto a voice-modulated mirror to carry speech. At the receiver side, the modulated sunlight fell on a photoconducting selenium cell that converted the message

into electrical current, and a telephone receiver produced the sound.

As with many early prototype inventions it was not without its faults, hence the significance of the Photophone was never realized until fiber-optic cables had been developed.

Today's optical fibers are flexible silica glass fibers although not to the extent of creating right angles without breaking. The flexibility is accomplished by carefully encasing the glass in plastic jackets for support while bending. Light is sent along the fiber and a light-sensitive diode detects the light pulses at the receiver. Optical fiber communication has several advantages (Comer, 2001). Optical fibers can carry more information (channels) over longer distances with fewer repeaters. They are much lighter than copper; therefore, they occupy less volume in underground cabling ducts. They are immune against electrical interferences, and difficult to tap into without

Figure 1: Alexander Graham Bell's Photophone

causing detection. For the same bandwidth, copper-wired systems consume more power, even more for wire pairs, to carry the signal than the optical fibers counter part. Therefore they keep the running cost of the system low. Despite all that, optical fibers have some disadvantages. Optical fibers are more expensive per meter than copper wires, although the sand is cheaper and abundant. However, the same fiber can carry far more information than the copper and fewer repeaters would be required for longer distance communications, keeping the overall cost at a minimum. Other drawbacks involve the difficulties in joining fibers together and finding breaks. This requires special equipment and training.

Evolution

Originally, the light sources were narrow bands of optic radiations in the form of a laser, which provided high-capacity optical communication. The lasers were not guided like today's fiber-optic cables and suffered similar problems encountered by Bell's Photophone atmospheric interference. A clear line of sight was required between transmitter and receiver for successful transmission. However, the lasers produce an invisible beam that if shone into the human eye could cause damage.

This new development inspired developers to continue to research the technological constraints. The major limitation to overcome was the need to guide the light while providing the ability to actually bend it away from the straight line. Another drawback of this early optical technology was the opaqueness of the glass, which hindered research from possible longer distance communication (Palias, 2005).

The first low-loss fibers were introduced in 1970 (Palias, 2005); this accomplishment triggered the rapid development of fiber-optic communication, leading to the rapid conversion of communication systems that previously relied on copper-wired technology to the faster and more efficient fiber-optic systems.

Today's technology is breaking communication barriers that were originally believed unfeasible. Initially the optical LANs were only expected to connect buildings to create a larger LAN. The first optical Ethernet standard specified a single 2km optical repeater, but their spans were limited by the maximum delay that could be allowed on an Ethernet LAN while still detecting collision. The switched Ethernet LANs were further expanded by bridging the gap between two or more individual buildings.

As optical links terminated at the switch ports, network performance was enhanced providing better network traffic control. To necessitate this process, the spanning-tree protocol (802.1D) was developed, which implemented path protection. Optical fiber technology could now enhance full-duplex transmission, which instantly doubled the bandwidth available. However, optical fiber LANs were only constrained by the distance that the lasers (light-emitting diodes) could reach.

In the next sections, we will examine different LANs expansions and connections based on optical communication. The following section gives an overview on the nature and properties of light when used in fiber-optic cables.

THE NATURE OF LIGHT

Light is often interpreted in different ways when dealing with different experiments. Sometimes it behaves like a wave and other times it behaves as a particle. In the context of this chapter we will look at light as being an electromagnetic wave with very high frequency and very short wavelength. The range of electromagnetic frequency is shown in Figure 2 (Nave, 2006).

The light frequency spectrum can be divided into three general bands:

infrared: wavelength is too long and is invisible to the human eye,

visible: wavelength is visible to the human eye,

ultraviolet: wavelength is too short and is invisible to the human eye.

For fiber-optic communications, the carrier frequency range from about 200THz to 370THz, which falls within the infrared spectrum. It is more common to measure higher frequency spectrums such as light in terms of wavelengths. A wavelength is the distance between repeating units of a wave pattern. The length of the wave depends on the frequency as well as the velocity of light, $\lambda = c/f$, where λ is the wavelength (meters), c is the speed of light and f is the frequency (Hz).

Light Characteristics

The light travels in the free space with the speed of 3×10^8 m/s. However its velocity is reduced when it crosses substances with higher densities (refraction index) than

Figure 2: Electromagnetic spectrum (Nave, 2006)

Figure 3: Reflection and refraction

the free space, causing the light rays to be distorted (Tomasi, 2001). The speed of light in a given medium can be evaluated as $c_m = c/n$, where n is the refraction index of the medium and c is the speed of light in the free space.

Reflection: The law of reflection specifies that when a light ray is impinging upon a reflective surface at the angle of incident θ_1 , it will be reflected from that surface with the same angle, $\theta_1 = \theta_3$, as shown in Figure 3.

Refraction: When a light ray passes from a material of a given density to another material with higher density, it bends toward the norm. Conversely, if it travels to a material with lower density it bends away from the norm (Tanenbaum, 2004, 94). Snell's law computes the angle of refraction for a given incident angle. The critical incident angle is defined as the angle that causes a 90-degree refracted ray from the norm, $\theta_1 = \sin^{-1}(n_2/n_1)$. This will only occur when the incident ray travels from a higher refraction index to a lower refraction index media, $n_2 < n_1$. Optical fibers operate on the principle of the total internal reflection of light. The light travels along the walls of the fiber, hits the wall at an angle larger than the critical angle and is reflected off the wall throughout the transmission.

Fiber-Optic Cable

A fiber-optic cable, as illustrated in Figure 4 (Tanenbaum, 2004), consists of four parts:

Figure 4: The structure of a fiber-optic cable

core: thin glass center of the fiber in which light travels in a zigzag mode using the cladding as the reflecting medium, with a total internal refraction,

cladding: outer optical material surrounding the core that reflects the light back into the core,

buffer: coating: a protective layer, which prevents the fiber from damage and moisture,

jacket: a protective layer made of PVC or Teflon to protect one or a bundle of fibers against moisture, abrasion, crushing and so on.

Classification of Optical Fibers

Optical fibers are classified into two categories: single-mode fibers and multimode fibers. The modes refer to the propagation characteristics of an electromagnetic wave as it travels through a particular type of fiber. In a single mode, rays of light travel in one direction along the center of the fiber. In multimode, rays of light travel in many directions through a number of paths. The single mode fiber is usually used in long-distance transmission such as telephony and multichannel broadcast systems, whereas the multimode fiber is best for short-distance transmission such as LAN systems and video surveillance (Fiber Optics, 2005).

Single-mode fiber: The single-mode fibers (see Figure 5) have a smaller diameter (6–8mm) and lower density than that of multimode fibers. As a result, the critical angle of the light beam is closer to 90 degrees making the propagation of different light beams almost horizontal, thus lowering the signal distortion by minimizing its dispersion (Forouzan, 2007). Usually, laser diodes are employed as the source of light to cover distances reaching up to 50km.

Multimode fiber: The multimode fibers have larger diameters (50–1,000 μm), which allow multiple beams from a light source to travel through the core in different paths, resulting in different arrival times at the end of the fibers. Multimode fiber is further divided into two categories: step-index fiber and graded-index fiber.

Step-index fiber: In step-index fiber, the refraction indexes of the core and cladding are uniformly distributed over the whole substance. The core's index is higher than that of the cladding hence causing a total internal reflection when the light enters the core at an angle greater than the critical angle.

In Figure 6, three rays of light waves travel in different direction down the core. The first travels straight down the center of the core, the second travels in a steep angle, which is reflected back and forth, and the third one is refracted into the cladding. The second ray travels a longer distance than the first one, thus both arrive at the destination at different times. This phenomenon is known as the

Figure 5: Single-mode fiber

Figure 6: Total internal reflection in multimode step-index fiber

Figure 7: Multimode graded-index fiber

modal dispersion, which causes a signal distortion at the receiving end and therefore, limits the transmission rate. Graded-index fiber: Graded-index fiber is manufactured in such a way that the refractive index of the core gradually decreases from the center of the core toward the cladding. This design speeds up the rays traveling away from the center as they travel through reduced refractive indexes. It therefore permits most rays to arrive at the receiver at the same time. Figure 7 depicts the light rays following a serpentine path. It gradually bends back toward the center by the continuously declining refractive index, hence reducing the pulse spread. In reality, the optical source of light emits several different wavelengths that travel at different speeds. The graded index at the core, similar to the single mode, causes a different pulse spreading called chromatic dispersion. Lasers are monochromatic sources of light which, when utilized, reduce the effect of chromatic dispersion.

Losses in Fiber-Optic Cables

There are several factors that complicate the transmission in optical fibers. These can be classified as linear and nonlinear effects. The linear effects increase with the length of the fiber. It includes the attenuation, the dispersion and the polarization.

Attenuation: Attenuation is result of the progressive amplitude reduction, loss in power, of the light ray traveling through the fiber. Attenuation is caused by absorption and scattering of light by the impurities. Absorption is also caused by the presence of Hydroxyl molecule (OH^-) found in the glass during the manufacturing process. Figure 8 shows the lowest attenuation in the silica measured in various wavelengths (Refi, 1999). There are three regions in the diagram, which are highlighted in grey; these regions are referred as the principle “window.” There are also several peaks that can be seen in the wavelength near 950 nm, 1200 nm, and 1380 nm where these peaks indicates the highest number of OH^- impurities, possibly caused by excess water remnants during the manufacturing process or humidity of the surrounding environment, which causes attenuation to occur.

The first window represents the 850 nm wavelength. This window was first utilized in step index multimode fibers. However, as a result of the problems of high optical loss of 3 dB/km, the transmission distance was shortened to about a kilometer as signals beyond that distance are distorted and unreadable. As such, the graded-index fiber is introduced where it utilizes the second window with a wavelength of 1300 nm and offers lower optical loss of around 0.5 dB/km. The performance of fiber is improved as waves on the longer mode travel faster than that of a shorter mode. Thus they arrive at the receiver at around the same time, which greatly reduces the effect of modal dispersion (Greenfield, 2002). The third window was later discovered by Nippon Telegraph and Telephone (NTT) in late 1977, which utilizes wavelengths of 1550 nm and is used in single mode fibers that supports higher bandwidth as well as lower optical loss of about 0.2 dB/km. As a result, fiber of this type is usually used for long haul transmission, whereas multimode fiber is used for short-range transmission, usually within or between buildings.

Absorption happens when lights are absorbed by impurities found in the glass fiber and are converted into heat or vibration. Compared to scattering, absorption accounts for a very low percentage of the overall attenuation problem, 3% to 5%, and can be improved by reducing the number of impurities in the fiber. In the 1380 nm region the OH^- peak was successfully eliminated resulting

Figure 8: Attenuation (dB/km) in a silica-based optical fiber (Tanenbaum, 2004, 95)

in a zero-water-peak-fiber (ZWPF). On the other hand, wavelength over 1700nm cannot be implemented in optical fiber communication as it suffers from high losses from infrared absorption (Alwayn, 2004).

Unlike absorption, Rayleigh scattering is a problem where light is diverted from its original angle while traveling along the fiber core as it interacts with the silica molecules in the fiber. In the event where the light is scattered, it will be diverted in a backward direction or out of the fiber core. Such an event contributes to 96% of the attenuation problem. Only when the light is diverted in an angle that supports forward traveling can attenuation be avoided. Short wavelengths experience higher scattering than long wavelengths; this can be seen in Figure 8. Notice that wavelengths shorter than 800nm are having higher attenuation. This is because wavelengths below 800nm suffer high scattering and therefore cannot be used in optical fiber communication.

Dispersion: Dispersion is because of the arrival of multiple wavelengths to the receiver at different times causing a spreading in the pulse and hence reducing the transmission rate. In single-mode fiber, a pulse containing several wavelengths broadens itself at the receiver producing an effect called inter-symbol interference. This phenomenon is referred as chromatic dispersion. The refraction index difference in the fiber also causes different traveling speeds among the wavelengths; this is referred to as material dispersion. The core has a higher refraction index than the cladding to ensure that light is to be reflected within the core. However, some of the lights might be propagated in the cladding and this will result in the broadening of the pulse as light in the cladding travels slower than that in the core as a result of lower refraction index. This phenomenon is known as waveguide dispersion. Modal dispersion is caused by delay differences among wavelengths traveling in different paths in a multimode fiber.

Polarization mode dispersion: A fiber core is generally seen as a cylindrical waveguide with a constant diameter. However, in actual fact a fiber core can have a different refraction index, geometric irregularity, temperature difference and stress placed upon the fiber. All these factors can cause two orthogonal polarization (vertical and horizontal) modes travelling at different speeds through the fiber, thus causing a difference in propagation time as one is travelling faster than the other. This phenomenon is referred to as differential group delay (DGD), which is measured in picoseconds.

In short, all these can be referred to as polarization mode dispersion (PMD), which according to Vivek Alwayn, is the result of “asymmetric distortions to the fiber from a perfect cylindrical geometry” (Alwayn, 2004). Polarization mode dispersion usually affects high-speed optical

networks with a bit rate higher than 5Gbps, which is used in long haul transmission (Lefebvre, 2001). Finally, nonlinear effects are problems caused by the optical signal power. For instance, scattering and four-wave mixing are such examples.

Fiber-Optic Communication System

A general fiber-optic system (see Figure 9), similar to other communication infrastructures, has several components. The information source produces various types of information such as voice, data, and video. The encoder encodes the information into different formats indicated by the underlying technology and then passes them to the transmitter. The transmitter serves as a light source, which launches the light into the fiber optic cable as well as a modulator that performs either analogue or digital modulation, for modulating light to represent the binary data that it receives from the source. The light source is either a light emitting diode (LED) or a laser diode (LD). Both LD and LED share the same characteristics. They emit light precisely within a small area, they have a long lifespan and they can be modulated at high speed. However, they differ in many instances. LD has a smaller spectral width compared to LED, hence it is able to couple more source power into the fiber and subsequently reduce attenuation. As such, LED can only be used in multimode fiber, whereas LD can be implemented in both multimode and single mode fibers. LD is more expensive than LED (Schneider, 2004).

A channel coupler feeds power into the information channel, before the light is transmitted into the fiber-optic cable, and then couples the emitted light. The information channel is made up of either glass or plastic fiber optics, which guide the light waves from the transmitter to the relay nodes and from the relay nodes to the receiver. The relay nodes may consist of optical amplifiers, repeaters, or switches (transparent or opaque) (Greenfield, 2002) that route and regenerate the signals in long distance transmission, if required. The receiver is either a PIN (p-type-intrinsic-n-type) diode or an avalanche photodiode (APD) where both sense light and convert it into an electrical current. However, the optical signal from the fiber optic cable and the resulting electrical current will have suffered losses. Consequently, the photodiode circuitry must be followed by one or more amplification stages. There may even be filters and equalizers to shape and improve the information-bearing electrical signal. The decoding part turns the modulated signal into binary form and delivers it to the information receiver.

OPTICAL LANs

The emergence of new high bandwidth-intensive multimedia applications make effective bandwidth allocation

Figure 9: Components of a fiber-optic communication system

in LANs an increasingly important issue. Optical fiber technology provides the bandwidth necessary to support such applications. Optical local area networks (optical LANs) transmit data to stations within a limited region that are in the same geographical space, for example in the same building. Shorter transmission distances decrease the error rates, for example when transmitting to stations within the same room; the error rates are approximately 10 to 12 (Palais, 2005). The signal within the optical LAN is split to accommodate all stations within the network; each station will receive a fraction of the power of the signal.

Single-Hop LANs

In the bus topology (see Figure 10) the signal transmitted by each station is coupled into the bus, and splits to supply each receiver. A disadvantage to this topology is the power asymmetries. For instance, the signal reaching a terminal from its predecessor terminal is stronger than the signal reaching it from the first terminal (Chapman, 1989).

LANs adopting a star topology (see Figure 11) use the power more efficiently, and facilitate a shared medium optical LAN. The star coupler combines the signals from the transmitters and splits it into n signals sent to each receiver (Walrand and Varaiya, 2000). Perhaps the constraint of this topology is the size and the number of ports of the coupler. This is a serious issue with network scalability.

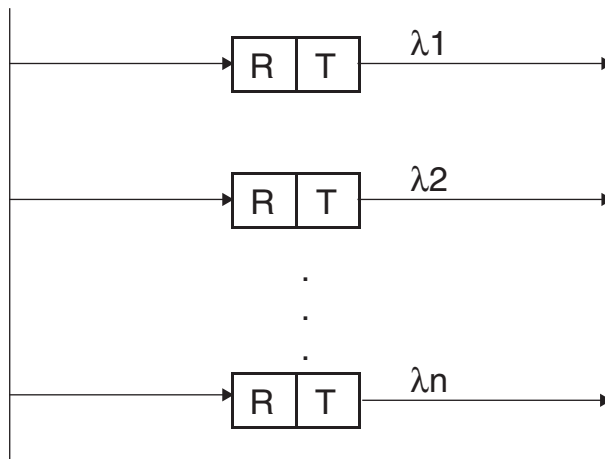

Figure 10: Optical LAN, bus topology

Figure 11: Optical LAN, star topology

Figure 12: Interconnected star topologies

Fortunately, cascading couplers on specific wavelengths, as shown in Figure 12, permit the network to expand further and cover a larger number of distributed stations.

An interconnection between two stations lasting for the length of a data packet is set up on the control channel, by the transmitting station that informs the receiving user where to tune in to receive the data packet. If the optical star is operated with a single wavelength then it operates at the same level as an Ethernet. All the stations hear all the traffic and pick off only those addressed to them.

In both topologies the signal from all the transmitters will broadcast to all the receivers. Each station transmits on one wavelength but receives all the wavelengths, therefore requiring a tunable transmitter or receiver to select the desired wavelength. The introduction of a control channel where any stations wishing to communicate are required to request resources provides a more powerful, although complex, network configuration.

Multihop LANs

Single-hop LANs do not scale easily and require tunable receivers, whereas the multihop configuration utilizes a fixed receiver and transmitter wavelength and are scalable. The eight-station shuffle network configures each station to receive and transmit two wavelengths. The assumption is that the wavelength conversion is possible at each station and can be used simultaneously on two different hops.

OPTICAL ETHERNET

Brief Review on the Ethernet

The classical Ethernet, operating on a speed of 10 Mbps, works on a bus topology under the control of the CSMA/CD

protocol located in the MAC sub-layer. Stations are tapped to the coaxial cable with transceivers. At both ends of the bus are terminators that remove the signal preventing it from reflecting back and hence interfering with the transmitting stations. The bus spans a maximum distance of 200 m or 500 m depending on cable type. CheaperNet or 10BASE2 expands to 200 m, and ThickerNet or 10BASE5 expands to 500 m, at which point the signal degrades to a level where repeaters are required to boost the power into the signal.

Stations asynchronously compete for the line—cable—to transmit their frames. The contention mechanism is based on the carrier sense multiple access with collision detection (CSMA/CD). When a station receives a packet to transmit, the circuitry of the network interface card (NIC) senses the line. If the line is busy—a transmission is in progress with bit transitions occurring in the medium—the station waits until it becomes idle. When the line is idle, the station transmits the frame. There are several variants to this protocol regarding the behavior of the sending station after the line is detected idle. In the Ethernet, the station immediately transmits when the line is available after a predefined inter-frame gap. It may happen that two or more stations attempt a transmission at the same time. If this is the case, a collision occurs. The protocol has the capability to detect collisions and force the stations involved in the collision to back off for random times before attempting a retransmission.

Bus, Star, Mesh, and Hierarchical Topologies

Ethernet has adopted various interconnections, including the star topologies with the hub or the switch at the center connected to all the stations via a RJ-45 connector. To scale and expand the LAN further, multiple switches with possibly different speeds and levels of routing—layer 3 switching—are interconnected in mesh configurations. Such topologies have to be carefully planned, possibly adopting a virtual LAN (VLAN), to achieve the maximum bandwidth and manageability. Hubs or switches can be connected in tree configuration forming a deep hierarchy of switches or hubs with stations located at the leaves.

Although electrical cables link most Ethernet LANs, fibers offer other advantages. Fibers are electrically noiseless, less dense than wires, therefore easy to put in building conduit, are more highly secure, and support much higher speeds and distances than copper.

In the remaining subsections we trace briefly the evolution of the fiber Ethernet and its interconnection from half to full duplexes.

10BASE-F: The dominating technology based on 10BASE is the twisted-pair copper. However, several fiber standards—10BASE-FL (fiber link), 10BASE-FB (fiber backbone), 10BASE-FP (fiber passive), and FOIRL (fiber optic inter-repeater link)—have been developed to target different market needs. Perhaps the success of the twisted pair was because of the unused bandwidth of the fiber, as the signaling rate of 10 Mbps occupied a smaller fraction of it. Another reason would be the cost of the optical equipment.

Fiber connections require two separate lines, one for transmission and the other for reception. For link integrity, an active idle signal of 1 MHz (in FL) or 2.5 MHz (in FB), depending on the standard, is monitored. If the medium attachment unit fails to detect this signal, it declares the link as failed and prevents the station or the repeater from transmitting. Nowadays, many vendors optionally supply a link light on the medium attachments unit to give a visual indication of the link integrity status. Fibers for the 10BASE-F rely on multimode transmissions with core and cladding diameters of 62.5 μm and 125 μm respectively (Kadambi, Crawford, and Kalkunte, 1998). Although vendors have produced many methods to connect the fiber to the medium attachments unit, the Bayonet Fiber Optical connector, BFOC, and the ST are the most commonly used (Shah and Ramakrishnan, 1993).

In general 10BASE-F segments can span up to 2 km if used exclusively with 10BASE-FL and up to 1 km if used with the FOIRL. 10BASE-FB is mainly used to connect additional hubs or repeaters as it has the ability, in its design as oppose to FL, to signal remote faults between the two hubs. The maximum distance that this fiber extends to is about 2 km, although when used with other standards, it would span up to 1 km. Finally, 10BASE-FP implements a rather different topology. The stations are connected to a passive hub forming a star topology, similar to Figure 11. The passive hub is convenient in places where electrical powers are hazardous and impractical in some areas. The hub floods the light pulses on all its ports without converting them to electrical signals. Hence, if many light pulses occur simultaneously at the hub, the signals interfere, causing collisions. Figure 13 depicts a possible mixed topology with all the optical connections following the IEEE restriction on the fiber length. It must be noted that the collision domain rather than the attenuation constraints limits the length of the fiber.

The collision detection capability is a function of the bus length, D , and the Ethernet frame length, L , at the NIC transmission rate of R Mbps, and the speed of the wave in the medium ($\text{cm} = c/n$),

$$\frac{L}{R} \geq \frac{2Dn}{c} + \varepsilon \quad (1)$$

in which c is the speed of light, n is the refraction index of the core, and ε in μsec is the latency associated with all repeaters or hubs and stations along the link. L_{min}/R refers to the collision domain, which defines the minimum frame size to be transmitted to detect a collision. Two or more transmissions occurring within the collision window (left hand side of the inequality (1)) will indisputably result in a collision. The minimum frame size for a 2,500-m bus, or five ThickNet segments, with four repeaters at the transmission speed of 10 Mbps is about 512 bits, which on the worst-case scenario permits a station to detect a collision effectively (Stallings, 2002). This indication permits the fiber links to span a maximum distance of 2 km with the same safety margin indicated in inequality (1).

100BASE-F: To satisfy applications demanding higher bandwidth, Ethernet has been driven into two complementary directions. One is the switched Ethernet where a

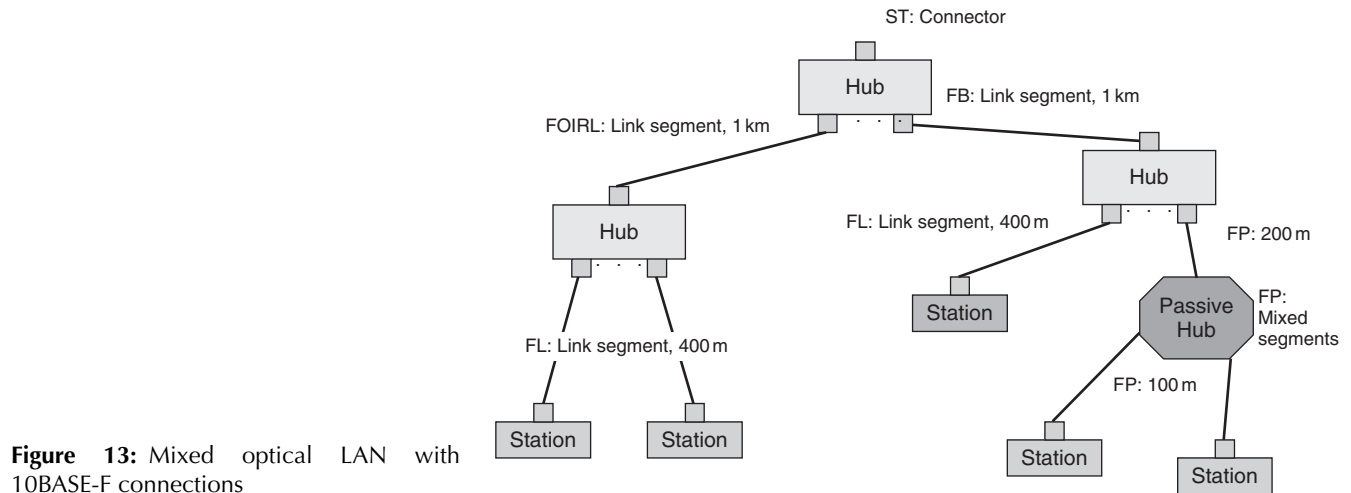

Figure 13: Mixed optical LAN with 10BASE-F connections

switch replaces the central hub, and therefore provides a full-duplex connection without a collision, and the other one is the faster Ethernet, where the clock or the speed of the NIC is increased by a factor of 10, yielding 100-Mbps transmission. In the former, restrictions on the length of the fiber are only imposed by the attenuation factors, and therefore larger topologies can be supported. In general, it is used in long-haul communications such as establishing connections between buildings. In the latter, the increase of speed to 100 Mbps requires a decrease in the fiber length by a factor of 10. Although the fiber connections based on switched Ethernet are desirable, there are design areas where mixtures of topologies have been configured. 100BASE-FX, the only standard in this class, has a much smaller geographical limit, a maximum length of 400 m. It is noted that with a mixed topology, using class I hubs, the maximum span of the fiber would be 130 m to 160 m (Kadambi, Crayford, and Kalkunte, 1998). 100BASE-FX uses two strands of graded-index multimode over a pair of fibers, 50/100 μm , or 62.5/125 μm .

The signaling speed in 10BASE is 20 MHz with Manchester encoding. However with 100BASE the same encoding technique would have required a clock of 200 MHz. Instead, 100BASE-FX, similar to 100BASE-TX, adopts the 4B/5B-encoding scheme, as shown in the simplified diagram in Figure 14. With this code four data nibbles are converted into 5 binary codes, chosen out of the 32 codes.

Two classes of hubs have been designed to permit interconnections with 100BASE media types.

Class I hub supports all 100BASE media types. This flexibility comes at the price of high latency that is induced when the hub converts from one code to another, and therefore reduces the length of the cable or the fiber. For instance, 100BASE-TX and 100BASE-FX use 4B/5B-coding scheme, 100BASE-T2 uses PAM 5X5 codes, and 100BASE-T4 uses 8B/6T codes. When 100BASE-FX is deployed with a class I hub within the mixed topology of 100BASE-T2 and 100BASE-T4, the maximum length of the fiber, limited by the collision domain, refer to inequality (1), would be 130 m. Whereas, when the class I hub connects only 100BASE-TX and/ or 100BASE-FX, the length of the fiber can be extended to 160 m.

Class II hubs are a two-hub topology with a 5-m separation between the hubs. It supports only 100BASE-TX and 100BASE-FX, therefore eliminating the code conversion process. This reduction gains extra spanning, and allows the fiber to extend up to 200 m, from the station to the hub. Figure 15 illustrates a mixed topology of 100BASE-TX and 100BASE-FX with class I hub and class II hub, and the switches operating on full and half duplex. Manufacturers usually design hubs, and switches with different delays; these have to be taken into consideration when designing mixed optical LANs.

1000BASE-F: Increasing the speed to 1000 Mbps will result in a decrease of 100 times in the length of the segment. Theoretically, the length of the segment in a half-duplex connection would be 20 m (Tanenbaum, 2004). This limitation is unacceptable for such a high transmission rate technology, especially when used with fiber-optics.

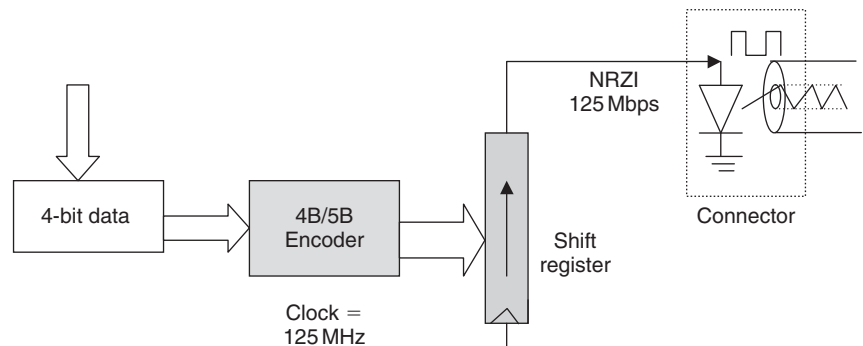

Figure 14: Encoding sequence for 100BASE-FX, which adopts the 4B/5B-encoding scheme

Figure 15: Mixed topology with 100BASE-FX length restrictions

Several design mechanisms have been deployed to overcome these limitations while maintaining the compatibility with predecessors, 10BASE and 100BASE standards. The efforts of the IEEE 802.3z task force went with the proposal of a carrier extension. This scheme involves changing the collision domain (time slot) from 512 bits to 512 bytes (4096) to maintain a segment of 8 times longer. The approach requires that frames of less than 512 bytes in size have to be padded by extra bytes, called extensions with special codes. Certainly, these extra overheads would reduce the efficiency of the Gig Ethernet to 12% (Haddock, 1996). Several approaches have been proposed to increase the efficiency to 76% (Molle, 1997) at least to match the 100BASE efficiency. Mainly, the frame bursting that involves sending several frames within a burst limit (65536bits) has been approved and adopted by the IEEE 802.3z task force (Haddock, 1996; Kalkunte, 1996).

The simplest approach would be to abolish the half duplex completely and connect stations to switches, thus removing the collision domain restrictions. This approach is becoming more popular as the prices of the switches are dropping. Furthermore, an adoption of fiber solutions with cheaper switches would be a more realistic and popular solution. With full-duplex connections, the worst-case normalized efficiency would be 76% for an interframe gap (IGP) of 96 bits and a minimum frame size of 512 bits. However, the major problem with full-duplex switched fast Ethernet is the congestion. Substantial losses of frames would lead to poor link efficiency. To overcome these challenges, the switching mechanism adopts one of the many control flow schemes to minimize frame loss, and hence avoid significant drops in the links efficiency.

One simple approach is for the switch to insert a carrier in the congested links forcing senders to wait until the congestion is over. More formally, IEEE 802.3x defines a PAUSE frame that indicates how long a sender will back off before attending a new transmission.

One of the key issues to the control flow is when to initiate and how long to wait for the control flow. With fiber links running at 1000 Mbps, significant buffering capacity would be required at the senders end, as several frames might be on transit before a PAUSE frame is received. The current technology designs switches with faster processing time to return the PAUSE frame immediately, and hence keep buffering capacity to a minimum.

Watermarks flow control is a technique that initiates the PAUSE frame when the number of frames received by the switch exceeds the low-watermark threshold, providing a safeguard to receive additional frames while the PAUSE frame is in transit. The credit-based control on the other hand, similar to ATM, assigns a number of credits for each sender. Upon congestion, the switch signals the senders with a smaller number credit to regulate their transmissions. The most interesting control flow is the rate-based flow. Upon receiving a control flow frame, the sending station adjusts its IGP to slow down the transmission. The new value of the IGP is part of the control flow frame (e.g., PAUSE frame), this approach smoothes the traffic through the switch, even at a higher rate.

At the physical layer, 1000BASE relies on fiber channel (FC) technology for connecting high-speed devices. The coding sub-layer of the physical layer, that implements Manchester encoding in 10BASE and 4B/5B encoding in 100BASE-TX, supports IBM 8B/10B code, which has an effective performance (Widmer and Franaszek, 1983). A very simple implementation of the code is to partition it into 5B/6B and 3B/4B subordinate coders. Furthermore, the physical medium dependent sub-layer relies entirely on FC0, fiber channel layer 0, dealing with connectors, and optical interfaces.

1000BASE supports two different media types: namely 1000BASE-SX (short wavelength laser) and 1000BASE-LX (long wavelength laser). 1000BASE-SX uses short wavelength laser in the region of 850 nm over a multimode fiber 50/62.5 μm . 1000Base-LX uses long wavelength laser 1300nm over multimode fiber 50/62.5 μm and

Figure 16: Mixture of 1000BASE cabling

single-mode fiber 2/10 μm . The multimode covers a distance from 220m to 550m, whereas the single mode spans over distances of 5km. Figure 16 depicts a possible network topology of 1000BASE-SX and 1000BASE-LX.

10GBASE-F: Although this technology may not be deployed now for LANs, except for parallel systems and high-speed servers, it is more attractive and appealing in the market of carrier networks. The speed of 10Gig Ethernet is about SONET, SDH, and OTN. It is worth mentioning that the success of Ethernet is its simplicity and low cost. These features would be carried over to the WAN, where the 10Gig Ethernet will play a major role. Ethernet equipment would be able to connect network premises to network carriers at no additional cost, induced by the use of SONET or SDH interfaces. It is expected that 10Gig Ethernet will interconnect LANs, MANs, and WANs.

The design of 10Gig Ethernet and possibly 100Gig Ethernet rely on full-duplex operation, with connections to switches (e.g., layer-3 switching) or routers. The optical fiber segments would only be limited by the attenuation factors. Currently, the technology permits 10Gig Ethernet single mode optical fibers to span a distance of up to 40km.

Although 10Gig Ethernet was intended to be entirely supported by optical fibers, IEEE802.3 committee has proposed two standards for 10Gig Ethernet over cable. 10GBASE-CX4 operates over limited distances from 15m to 30m over 4-pairs of TWINAX cable each running at the data rate of 3.125Gbps. With the 8B/10B encoding, this standard gives the required 10Gbps. The goal of this standard is to support low cost inter-rack solutions.

10GBASE-T operates at full duplex with Category 6 (class E) and Category 7 (class F) for up to 100m with four twisted-pair copper. Category 7 is adequately specified for this bandwidth; however, Category 6 would require performance characteristics beyond 250MHz to 450MHz. 10GBASE-T achieves the 10Gig speed by deploying 10-level PAM signaling with 3-bit per level, over four lanes of 833Mbps, yielding an aggregate transmission rate of 10Gbps. This technology offers cheaper installation over

fibers. The market would target data centers and horizontal enterprise networks.

Although 10GBASE is similar in every way to its predecessors to maintain compatibility with the reconciliation sub-layer, it differs in the physical layer, as it is meant for different purposes. The encoding techniques utilized in the PCS, physical coding sub-layer, are the 8B/10B, similar to 1000BASE, and the 64B/66B. The IEEE 802.3 task force has used the suffix “X” to refer to the 8B/10B-encoding scheme. On the other hand, the physical layer implements different wavelengths and fiber modes. For instance, the suffix “S” refers to 850nm wavelength with a serial transceiver on two multimode fibers. The suffix “L” refers to 1310-nm-long wavelength with a serial transceiver on two single-mode fibers. The suffix “L4” refers to 1310-nm-long wavelength with four wave division multiplexing, WDM—the interested readers may refer to other chapters of this handbook for more details about WDM—on a two multimode or two single-mode fibers. Finally, the suffix “E” refers to 1550-nm extra-long wavelength with a serial transceiver on two single-mode fibers. These standards can be combined to create several media types for the optical 10GBASE Ethernet.

10GBASE-LX4 or simply 10GBASE-X utilizes 8B/10B-encoding scheme at the PCS sub-layer, with four WDM and a long wavelength, 1310nm, over distances of 300m (multimode fibers) to 10km (single-mode fibers). This would be a possible candidate for MANs, when the entire infrastructure is Ethernet-based to avoid any protocols or framing conversions. 10GBASE-SR, -LR, and -ER or simply 10GBASE-R uses 64B/66B encoding schemes. They deploy short wavelength, 850nm, on multimode fibers, long wavelength, 1310nm, on single-mode fiber, and extra-long wavelength, 1550nm, on single-mode fibers over distances 65m, 10km, and 40km respectively. This technology is intended for LANs and WANs where the infrastructure is all Ethernet-based. Finally, 10GBASE-SW, -LW, and -EW, or simply 10GBASE-W uses the same technology as 10GBASE-R with the exception of an additional sub-layer, called the WAN interface sub-layer (WIS). This sub-layer permits 10GBASE-W to connect to SONET, which dominates the WAN market today. Most vendors believe that 10GBASE-W and the future versions will dominate the carrier networks rendering the entire public network a large optical Ethernet LAN. Figure 17 depicts a possible connection with the mixed interconnections of all the 10GBASE classes while maintaining the segments length restrictions. In full duplex, the length of the segment is only restricted by the attenuation that is proportional to the speed of the transmission and the distance of the fiber. For instance, LX4 spans a distance of 300m at the rate of 500MHz per km.

OPTICAL RING

Fiber distributed data interface (FDDI) has been the LAN standard operating at the speed of 100Mbps long before the 100BASE Ethernet was designed (Ross, 1986, 1989). It specifies a transmission over dual ring optical fiber primary and secondary rings, using token passing access protocol. Both multimode and single-mode fibers are

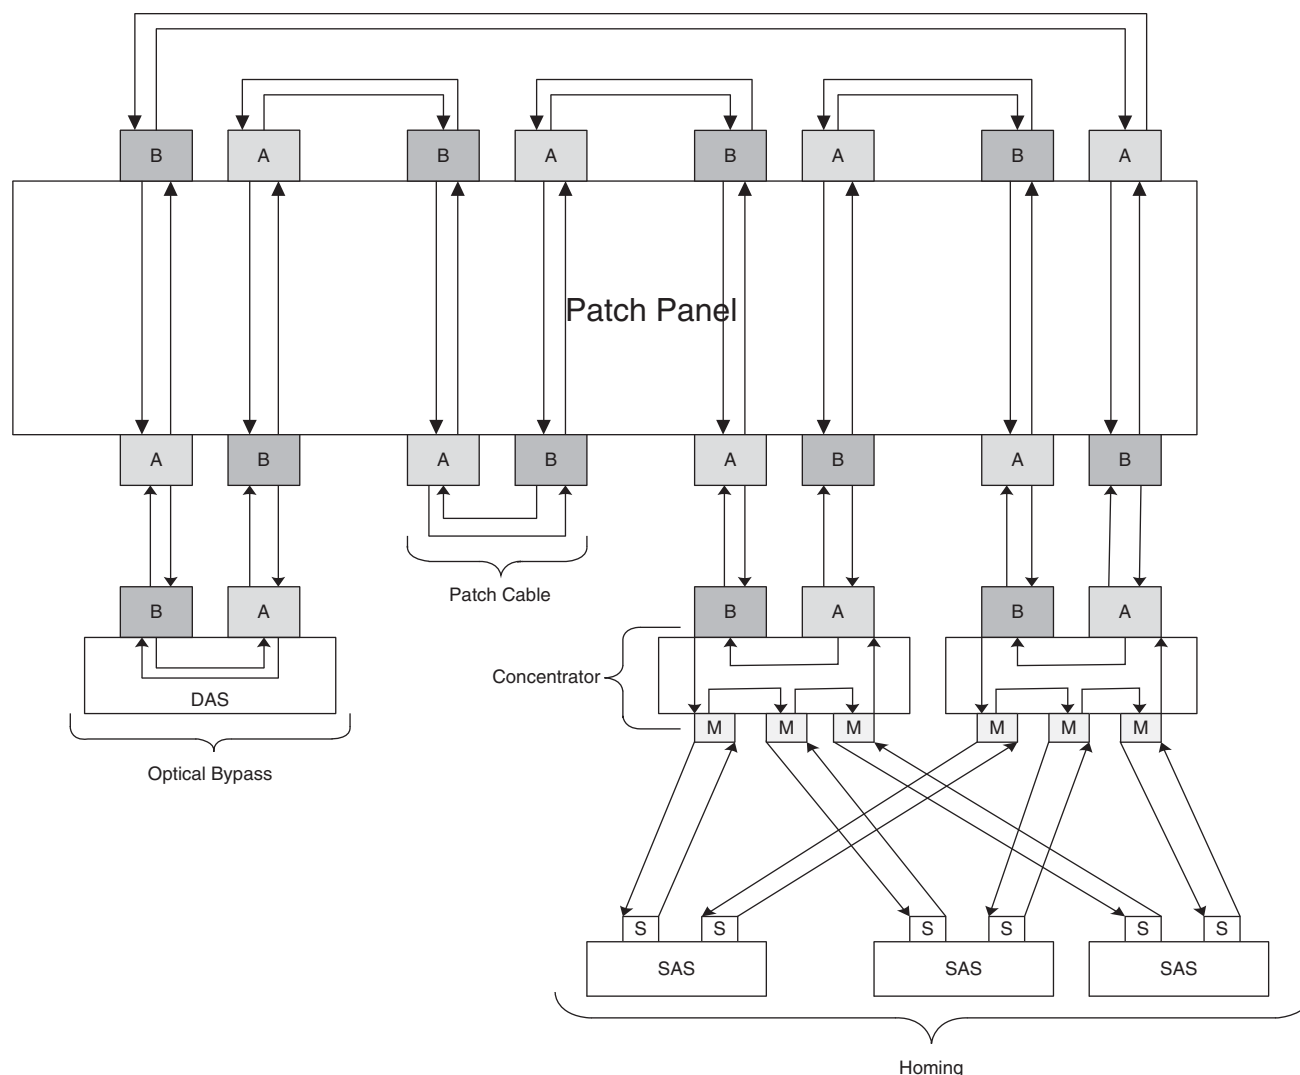

Figure 18: FDDI wiring connections, the connectors A, B, M, and S are different types to provide proper connections to the ring

To implement the access to the ring, FDDI deploys the same principle as the token ring. The management station plays an important role in maintaining a fair and efficient access to the ring. Both synchronous and asynchronous traffics can be supported at the same time (Joshi 1986). In particular, FDDI-II has optimal features in the MAC layer to provide QoS for delay-sensitive applications.

In general, FDDI uses timed token rotation protocol, which presets a defined value called target token rotation time (TTRT). The manager station adjusts this counter and broadcasts it to all stations sharing the ring. The counter (TTRT) plays an important role in the performance of the ring. Upon receipt of the token, a station transmits queued frames up to the time hold timer (THT), and then passes the token to the next station in turn. In this case, each station based on the actual traffic dynamically calculates the value of THT, which is utilized to maintain a fair access to the ring by all the stations, and hence defines the performance of the ring.

As shown in Figure 19, the maximum throughput of the ring increases with the target token rotation protocol.

However, the maximum access delay also increases, refer to Figure 20. A minimum value for the TTRT (4ms) can offer a good ring performance. In general, the maximum standard value for the TTRT can go as high as 165ms, producing a very high access delay.

THE INTERFACE BETWEEN FIBER AND COAXIAL

The growing impetus of broadband prompted the upgrade of the cable system to high-bandwidth fiber. This meant that the central core is fiber with coaxial cable connecting residential properties to the system; this model is termed the hybrid fiber coax (HFC). The electro and optical elements of the system are interfaced via an electro-optical converter called “fiber nodes.” These are “dumb” devices in that they do not interpret the signals and only provide an interface between the two media. The bandwidth of the fiber would then feed multiple coaxial cables via the

Figure 19: The maximum throughput attainable by the FDDI ring for a fiber of 500 m as a function of the number of attached stations for various TTRT

Figure 20: The maximum access delay attainable by the FDDI ring for a fiber of 500 m as a function of the number of attached stations for various TTRT

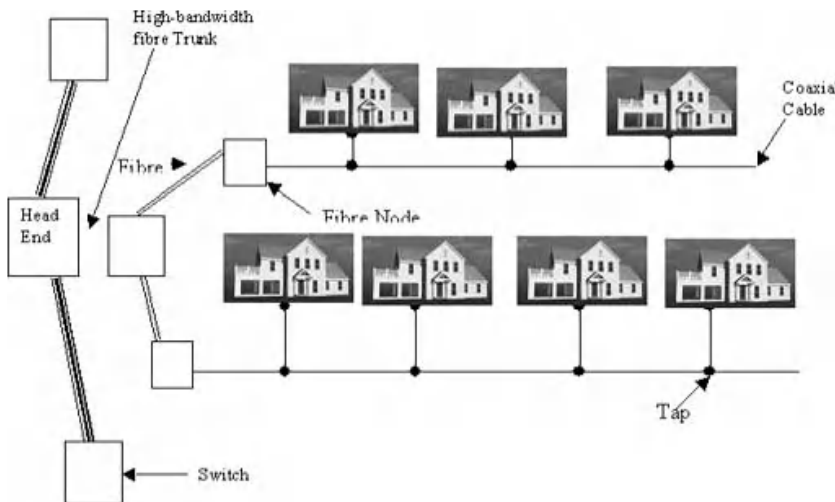

Figure 21: Broadband cable network for television using HCF

fiber nodes. By using frequency division multiplexing, an HFC network may carry a variety of services, including analog TV, digital TV (standard definition and HDTV), video on demand, telephony, and high-speed data. The fiber-optic cables connect the optical node to a distant headend (Figure 21).

OPTICAL INTERNET, MPLS, AND GMPLS MPLS

The realization of an optical Internet depends on the synthesis and standardization of protocols that work in a multivendor environment. "The number of carriers

Figure 22: Multiprotocol label switching (MPLS)

deploying new MPLS-based metro Ethernet equipment doubled between 2005 and 2006, from 42 percent to 84 percent” (Campbell, 2006).

Research in the IP community integrated the IP protocol into connection-oriented technology, with the aim to improve QoS providing a virtual circuit to support end-to-end packet transfer. Using a virtual path promotes efficient allocation of network resources via statistical multiplexing, enabling QoS assurances to be made as opposed to the “best effort” service provided by IP.

Multiprotocol label switching (MPLS) (Figure 22) is a suite of standard routing and signaling protocols that supports a variable length stack of four-octet labels at the beginning of an IP packet. It is the first of these labels that help the label switching router (LSR), utilizing the label-forwarding table, to determine the packet output port or the label-switch path (LSP). Connections established using MPLS build on current protocols, such as OSPF and intermediate system to intermediate system (IS-IS), to exchange link-state topology (Basak and Siket, 2000). MPLS can provide rapid restoration of packets in an IP network at the point of failure by rerouting to another LSP.

The label switching and packet forwarding processes are completely decoupled from how the LSPs are created and destroyed. The MPLS paradigm is much simpler than traditional IP routing allowing much larger numbers of packets per second to be processed (Ramaswami and Sivarajan, 2002). The major benefit of decoupling these functions in any optimization of packet forwarding will be autonomous of label-switch, which is not the case in IP routers.

There are synergies between MPLS, LSR, and optical cross-connects (OXC) and the MPLS, LSP, and optical channel trail. Similar to MPLS, OXCs need routing protocols, such as OSPF and IS-IS, to establish optical

resource availability for path computation. Also, similar signaling protocols such as RSVP and LDP are used to configure OXCs to establish optical channel trails. The Internet Engineering Task Force (IETF) has proposed MPLS as the model to adapt for optical devices. OXCs are emerging as the fundamental building block of a seamless optical transport network.

GMPLS

As explained previously, MPLS is used for label switched path (LSP) to provide traffic engineering and levels of quality of service (QoS). GMPLS extends the functions of the MPLS to connect devices that may switch on packets (IP), cells (ATM), time (TDM/SONET), wavelength (DWDM), and physical space (OXC). It also adds capabilities for provisioning and managing networks at a low cost. The most apparent features of the GMPLS for optical networks are connections and flexibility at the physical layer; the way labels are distributed and acquired, the way capacity is allocated to overcome congestions and bottlenecks, and the way networks failures are handled and reported.

GMPLS operates in two modes: overlay and peer models. In the overlay model, the physical light path is determined by the optical domain and not by the routers. The edge routers do not participate into routing protocol that runs among the core routers. The core routers apply their own protocols, possibly within the optical domain. On the other hand, in peer models, the IP routers determine the full path of the end-to-end connection. The edge routers interact with the core routers deploying the same protocols and routing. For more details, the reader may refer to RFC 3471 (Berger, 2003). For instance, as shown in Figure 23, to establish a path between LSR1 and LSR2,

Figure 23: A path is established between peer devices, using downstream hierarchy

tunneling is applied in the lower hierarchy. The path is formed, by first having the sender node to transmit a PATH/LABEL request message holding specific parameters required for the intended network. The downstream node then sends back a RESV/LABEL. When the initiator receives it, it creates a path with its peer via a RSVP/PATH message.

Finally, GMPLS has two planes: the data and the control planes. They might be physically or logically separated. For instance, the control plane might direct the control information via ETHERNET, X.25 connection, or use a slice of STS-1 (synchronous transport signal).

CONCLUSION

The demand for greater bandwidths is accelerating the distribution of fiber-optic communication systems. Fiber-optic cables have been successfully used in long-distance communication; with over 8% of the world's telecommunication systems now utilizing fiber-optic cables (Bellis, n.d.).

Telecommunication and cable companies have merged resources to distribute their services via fiber-optic cable to the home. This has led to standards being defined; these incorporate five key criteria.

- Ability to carry multiple protocols
- Maintain architectural flexibility
- Provide good diagnostic capabilities for signal quality and fault management
- Transparent data transport protocols
- Compatibility with data transfer methodologies

Although the increased performance and greater bandwidth has been attractive for LANs, economic considerations have limited its development in this area. With today's demands forever increasing bandwidth, coupled with the diminishing cost, fiber-optic LANs are becoming very popular in areas where copper connections have limitations. Fiber-optic cables are implemented in areas that have an electrically noisy environment or systems that carry sensitive data. There are also minimal issues with building regulations when implementing an optical fiber network as opposed to an electric cabled one.

Optical communication has migrated from the WAN and MAN to the LAN across many technologies: Ethernet, ring, and fiber channels. Such a leap might reach the internal architectures of the servers and the PCs. Instead of electricity, the stations will operate entirely by optics/photons hence breaking the barriers of speed and bandwidth limitations imposed by the electrons. Furthermore, optical wireless is an interesting domain that will be well accepted by the ad hoc network infrastructure, especially in large-scale ad hoc networks (Adda et al., 2005; Owen and Adda, 2005).

GLOSSARY

10 gigabit Ethernet: Ethernet at 10 billion bits per second over optical fiber. Multimode fiber supports

distances up to 300 m; single mode fiber supports distances up to 40 km.

1000BASE-LX: A fiber-optic gigabit Ethernet standard, using a long wavelength laser. Can work over a distance of up to 2 km over 9 μ m single-mode fiber.

1000BASE-SX: A fiber-optic gigabit Ethernet standard, that operates over multimode fiber using a 0.85-micrometer near infrared light wavelength. The specification allows for a maximum distance between endpoints of 220 m over 62.5/125- μ m fiber, although can usually work over significantly longer distances.

100BASE-FX: The IEEE Fast Ethernet standard for 100-Mbps Ethernet over fiber-optic cabling. It uses two strands of multimode optical fiber for receive and transmit.

100BASE-T2: 100-Mbps Ethernet over Category 3 cabling. Supports full duplex, and use only two pairs. It is functionally equivalent to 100BASE-TX.

100BASE-T4: The IEEE Fast Ethernet standard for 100-Mbps Ethernet over Category 3 UTP/STP. The IEEE Fast Ethernet standard for 100-Mbps Ethernet over Category 3 UTP/STP.

100BASE-TX: The IEEE Fast Ethernet standard for 100-Mbps Ethernet over Category 5 UTP/STP.

10BASE-F: 10-Mbps baseband Ethernet over optical fiber.

10BASE-FB: 10-Mbps baseband Ethernet over two multimode optical fibers using a synchronous active hub.

10BASE-FL: The implementation of the 802.3 standard designed to operate over fiber-optic cable at 10 Mbps.

10BASE-FP: A passive star network that requires no repeater.

Bandwidth: The data-carrying capacity of a transmission medium measured in bits per second (bps) or in cycles per second (cps) or Hertz (Hz).

Bridge: A networking device that connects local or wide area networks using the same or different data-link layer.

CDDI: Copper distributed data interface. Copper cable based implementation of FDDI.

CSMA/CD: Carrier senses multiple access with collision detection. The network access method used by Ethernet networks.

DAS: DAS is storage that is directly connected to a server by connectivity media such as parallel SCSI cables.

DCS: Digital cross-connect systems. It is software controlled and uses time-slot interchange to transfer slots between input and output lines.

Encoder: Encodes the information and passes them to the transmitter.

Ethernet: A 10-megabit per second (Mbps) baseband-type network that uses the contention-based CSMA/CD media access method. Invented by Robert Metcalfe at Xerox's Palo Alto Research Center in the mid-1970s.

FDDI: Fiber distributed data interface is a media access (transmission) control-level protocol with token-ring architecture, a communication bandwidth of 100 Mbps and supported on a fiber network medium.

Fiber-optic detectors: Can be either a PIN (p-type-intrinsic-n-type) diode or an APD (avalanche photodiode)

where both senses light and converts it into an electrical current.

FOIRL (Fiber-optic inter repeater link): An early implementation of a subset of the 802.3 10Base-FL standard designed to connect fiber-optic repeaters at 10Mbps.

FSPF: Fabric shortest path first is a routing protocol used in fiber channel networks. It calculates the best path between switches, establishes routes across the fabric, and calculates alternate routes in event of a failure or topology change.

GBIC: Gigabit interface converter; a fiber channel optical or copper transceiver that is easily swapped to offer a flexible choice of copper or fiber-optic media.

HBA: Host bus adapter, that plugs into a host enabling the host to communicate with a SCSI device.

IETF: The Internet Engineering Task Force is charged with developing and promoting Internet standards.

IS-IS: Intermediate system-intermediate system is an International Organization for Standardization (ISO) dynamic routing specification.

LAN: Local area network is a computer network covering a local area, like a home, office or small group of buildings.

LD (laser diode): Similar to LED but can be used in both single and multimode fiber as it has a smaller spectral width.

LED (light-emitting diode): Converts the electrical signal into a corresponding light signal that can be transmitted in the fiber. More reliable than lasers, but both sources will degrade over time because of heat and uneven current. Has a larger spectral width compared to LD hence can only be used in multimode fiber.

LSP: Label switched paths are often also referred to as tunnels. LSPs are used to transport data, such as IP packets, across an MPLS network.

LSR: A node that resides inside the MPLS domain boundary and does no IP forwarding.

MAN (metropolitan area network): A data network designed for a town or city. MANs are larger than LANs, but smaller than WANs.

Media access unit: An Ethernet transceiver.

MPLS: MPLS is a widely supported method of speeding up data communication over combined IP/ATM networks.

Multimode fiber: The most common type of fiber-optic cabling used in network installations. Typically, multimode has a core diameter of 62.5 microns and an outer cladding diameter of 125 microns. Nearly all fiber-based networking hardware (repeaters, switches, LAN cards) are multimode.

Multimode graded index fiber: The refractive index of the core gradually decreases from the center of the core toward the cladding. This reduces the problem of dispersion as most light rays arrive at the receiver at the same time. Usually used in short distance transmission, such as a LAN.

Multimode step index fiber: A sharp difference in the refractive index of the core and cladding causing total internal reflection as light moves along the cable. This suffers from dispersion as light rays travels along different path hence arrive on the receiver at different

times. Usually used in medium distance transmission, such as a MAN.

Network interface card (NIC): An adapter card providing the physical connection between a computer and the network medium.

Optical amplifiers: To strengthen the signals in a long-haul transmission to reduce the effect of dispersion and attenuation.

Optical fiber: Translucent fiber that can transmit beams of laser light. Ideal for reliable high speed LANs and backbones.

Optical fiber connectors: A mechanical or optical device that provides a demountable connection between two fibers or a fibers and a source or detector.

OSPF: Open shortest path first is a protocol used by routers on an IP network.

OTN: Open transport network.

OXC: Optical cross-connects, connects optical networks providing versatility and is reconfigurable.

Photophone: A wireless communication device using light to transmit signals through air, patented by Alexander Graham Bell.

PSC: Packet switch capable.

Receiver: A device that gets the packets from the communication network.

Router: A device that provides intelligent connections between networks. Routers operate at the network layer of the OSI model and are responsible for making decisions about which paths through a network the transmitted data will use.

SAS: Single stations are attached to the ring concentrator and mainly inject and remove traffic from the primary ring.

SDH: Synchronous digital hierarchy, the international standard for transmitting digital information over optical networks.

Single-mode fiber: A type of fiber that uses a single path for light transmission (i.e., the light is not reflected within the core). Single-mode fiber may support distances between 2 km up to 20 km.

SONET: Synchronous optical network, an international standard for high-speed communication over fiber-optic networks.

Spanning-tree protocol: The spanning-tree protocol is used to interconnect network switches.

Switch: A network device that selects a path or circuit for sending a unit of data to its next destination.

TCP: Transmission control protocol—A connection oriented transport protocol.

UDP: User datagram protocol—A connectionless oriented transport protocol. UDP is the transport protocol used by SNMP.

VLAN: Virtual LAN, a network of computers that behave as if they are connected to the same wire even though they may actually be physically located on different segments of a LAN.

WAN: Wide area networks, a computer network that spans a wider area than does a local area network.

WDM: For fiber channels, a variation of frequency division multiplexing is called wavelength division multiplexing.

HOW WINDOWS 2000 MANAGES INTERNET PROTOCOL: IP AND DHCP

Although the basic architecture of the Windows 2000 OS is based on components that were already widely in use at the time of its debut, it did introduce a number of new features. One example is its support for the dynamic host configuration protocol (DHCP), a consolidated standard that greatly simplifies administration of networks based on TCP/IP protocols. DHCP nicely resolves a series of very important practical problems, although there are a number of “collateral” aspects that require careful attention. In this chapter we address technical and implementation issues as well as security aspects.

Every computer connected to a TCP/IP network must have a single, unambiguous Internet protocol (IP) address. This address may be provided manually or automatically by the system administrator. Although the former option allows greater control and even an extra layer of security (especially regarding event traceability), the latter is incontestably the option of choice for large,

dynamic networks where manual operations cannot possibly play a structural role.

To address this situation, Microsoft has been working to develop the DHCP. DHCP architecture and functions are addressed by the RFCs 2131 and 2132. According to these documents, DHCP allows the automatic attribution of an IP address to a given machine as soon as it boots up or connects to the network. It also allows certain settings to be modified while the host is connected to the network.

DHCP is based on a series of components making up a central database of IP addresses, which—together with configuration information such as subnet masks, DNS, and default gateways—allow rapid and functional connection to the public network. As suggested above, the larger the network, the greater the advantages offered by DHCP. And as Microsoft says, this protocol also enhances Microsoft-based systems, which have the following characteristics:

Dynamic modification of configurations coming from a central location

In Windows 2000 Server, DHCP can interact with the DNS servers, thus avoiding the duplication of transiting information, enhancing both performance and security.

Again, in Windows 2000, the implementation of DHCP contains an advanced monitoring tool with customizable reporting features. This operating system has a series of security features such as multicast address allocation control, recognition of unauthorized or “fake” DHCP servers, clustering, and so forth.

Windows 2000 and DHCP: A Few Details

Windows 2000 added specific features into its architecture on the basis of Internet Engineering Task Force (IETF) recommendations. These features interact dynamically with DNS servers. In particular, given the fact that the IETF indications are not fully definitive in this regard, Windows 2000 can register pointers (PTR) and addresses (A) for its clients on a DNS server. In theory, this would provide stable visibility to DHCP clients even on public DNSs, obviously ones based on dynamic DNS (DDNS).

Put simply, this feature allows a Windows 2000-based DHCP server to act as a proxy for its clients, which are in turn based on other Microsoft operating systems. Looking at this in detail, DHCP servers based on Windows 2000 server are able to distinguish between the different types of clients, including those using Windows 2000, which are able to interact dynamically with DDNS servers. Here we should point out that static DNS and DHCP cannot interact on a basic level. Thus, it is not possible to ensure that name-address mapping is conserved. This could cause problems unless, as Microsoft recommends, using WINS lookup, which should be queried by the DHCP clients when they get configured. Here is what the official Microsoft literature suggests:

If WINS servers are used on a network, enable WINS lookup for DHCP clients that use NetBIOS.

Assign IP address reservations with an infinite lease duration for DHCP clients that use DNS only and do not support NetBIOS.

Wherever possible, upgrade or replace older static DNS servers with DNS servers supporting dynamic DNS service. Dynamic DNS service is supported by the Microsoft DNS server included in Windows 2000 Server.

Installation of DHCP in Company Networks

One of the first things to do when you decide to implement DHCP is to find out how many DHCP servers are necessary for your network structure. In a modest-sized local network with only a physical subnet and no routing, a single DHCP server may be enough. If you add physical routers you will have to increase the number of DHCP servers proportionally.

Although in theory there is no limit to the number of clients that can connect to a DHCP server, there is a maximum number of connections that can be handled practically. This relates mainly to factors such as machine processing power, network speed, disk capacity, and so on. One parameter not related to processing power is the

speed of network links. A slow link or, as an extreme, a dialup connection, requires a DHCP server on both sides. Additionally, many counsel the use of a multiple DHCP server with multicast functionality to ensure request coverage, even if one or more specific servers cannot be contacted.

Although every client computer has to have the right software to dialog with a DHCP machine running Windows 2000 Server, another factor to keep in mind is that of “scopes.”

According to Microsoft, a scope is an administrative grouping of computers into a subnet using the DHCP service. Administrators create a scope for each physical subnet, which is then used to define parameters used by clients for this subnet. Scopes can be created based on the needs of particular groups of users, with appropriate lease durations for each scope. A DHCP scope consists of a pool of IP addresses on a subnet, such as 10.223.223.1 to 10.223.223.200, that the DHCP server can lease to DHCP clients. Each physical network can have only one DHCP scope or a superscope with one or more ranges of IP addresses. Prior to actual deployment, every administrator has to define the scopes. This is a rather important task that also has security ramifications.

DHCP Server Authorization

Another DHCP server function under Windows 2000 is that of “authorizing” DHCP servers. Practically speaking, this amounts to a sort of access/authenticity control list, whose basic purpose is to prevent access by nonauthorized DHCP servers. In addition to ensuring against duplication during IP address allocation, it also limits problems related to hijacking and the like. The authorization process is carried out by the group of domain administrators specifically delegated to DHCP management.

Authorization is managed by active directory (AD), which is used here to keep a registry of authorized DHCP servers. AD also provides information on the status of each server so that requests may also be redirected to something other than the default resource.

Microsoft's instructions on setting up the resources are very clear: The list of authorized servers can be created in the AD through the DHCP snap-in. When it first comes up, the DHCP server tries to find out if it is part of the directory domain. If it is, it tries to contact the directory to see if it is on the list of authorized servers. If it succeeds, it sends out DHCPINFORM to find out if there are other directory services running and makes sure that it is valid in others as well. If it cannot connect to the directory, it assumes that it is not authorized and does not respond to client requests. Likewise, if it does reach the directory but does not find itself on the authorized list, it does not respond to clients. If it finds itself on the authorized list, it starts to service client requests.

There is a well defined procedure for checking authorization requisites. When a DHCP server that is not a member server of the domain (such as a member of a workgroup) comes up, the resource itself broadcasts a DHCPINFORM message on the network. Any other server that receives this message responds with a DHCPACK message and provides the name of the directory domain

to which it belongs. If a workgroup DHCP server detects another member DHCP server of a domain on the network, the workgroup DHCP server assumes that it is unauthorized on that network and does not service requests. If the workgroup DHCP server detects the presence of another workgroup server, it ignores it; this means that there can be multiple workgroup servers active at the same time, as long as there is no directory service. Even when a workgroup server comes up and finds itself allowed to run (because no other domain member server or workgroup server is on the network), it continues to probe DHCPINFORM every five minutes. If an authorized domain member DHCP server comes up later, the workgroup server becomes unauthorized and stops servicing.

This is a rather attractive feature, especially if you do not plan to invest in external tools or supplementary control architecture such as those based on network access control (NAC).

Security and the DHCP Audit

The Windows 2000 DHCP server has a number of fundamentally important auditing tools for those dealing with security and incident response. In the configuration step you will have to indicate the directory path where the system log files will be stored and specify the maximum size of the log files. The audit is not performed in real time, but on a scheduled basis. The administrator indicates how many times the DHCP server will have to write events before checking to see if the disk quota has been reached. From the DHCP console you can select the DHCP server to monitor: choose properties from the action menu, click the “advanced” tab and edit the audit log file pathway, if necessary. You can customize other settings on the configuration registry level.

IMPLEMENTING NAME RESOLUTION IN WINDOWS 2000 USING DNS

Windows 2000 vs. DNS: An Introduction

As described in the previous section, the Windows 2000 name resolution architecture is fundamentally compliant with RFC-2131 and RFC-2132. This means there is total

compatibility with other systems of the same type, and also with DNS.

Although not actually calling it obligatory, Microsoft naturally recommends the use of a DNS under Windows 2000. Even though this might seem motivated purely by commercial motives, the reason is actually practical. Windows 2000 allows interaction with AD, something that offers important advantages, partly because AD uses the multimaster replication engine, which ensures, among other things, faster propagation. Regarding interaction with the clients (excluding the outdated Windows NT 3.5 and 3.51, Windows NT 4.0, Windows 95, and Windows 98, which rely on NetBIOS that can use NBNS (WINS), broadcast, or flat LmHosts files), because DNS as implemented in Windows 2000 is Windows Internet Name Services (WINS)-ware, a combination of both DNS and WINS can be used in a mixed environment to achieve maximum efficiency in locating various network services and resources.

In this section it is assumed that a description of DNS is not necessary. However, the Table 1 helps clarify the way the database for this type of service is structured, keeping in mind that a DNS database consists of resource records (RRs). Each RR identifies a particular resource within the database. There are various types of RRs in DNS.

The structure of the DNS databases is described in the reference RFCs. There is an updated list (June 2006) of RFCs relating to the domain name system at <http://www.dns.net/dnsrd/rfc/>. Nevertheless, an overview of how to manage the database, with special reference to replication, might still be useful here.

As noted, a DNS database can be subdivided into multiple zones by a method known as partitioning. A zone is a portion of the DNS database that contains the resource records with the owner names that belong to the contiguous portion of the DNS namespace. Zone files are maintained on DNS servers. A single DNS server can be configured to host zero, one, or multiple zones.

The role of the root domain, the domain name to which a particular zone is associated and bound, is very important in this case. Starting from the premise that a zone contains information about all names that end with the zone's root domain name, a DNS server is considered

Table 1: DNS vs. RR

Description	Class	TTL	Type	Data
Start of Authority	Internet (IN)	Default TTL is 60 minutes	SOA	Owner Name, Primary Name Server DNS Name, Serial Number, Refresh Interval, Retry Interval, Expire Time, Minimum TTL
Host	Internet (IN)	Zone (start of authority [SOA]) TTL	A	Owner Name (Host DNS Name), Host IP Address
Name Server	Internet (IN)	Zone (SOA) TTL	NS	Owner Name, Name Server DNS Name
Mail Exchanger	Internet (IN)	Zone (SOA) TTL	MX	Owner Name, Mail Exchange Server DNS Name, Preference Number
Canonical Name (an alias)	Internet (IN)	Zone (SOA) TTL	CNAME	Owner Name (Alias Name), Host DNS Name

authoritative for a name if it loads the zone containing that name. The first record in any zone file is a start of authority (SoA) RR. The SoA RR identifies a primary DNS name server for the zone as the best source of information for the data within that zone and as an entity processing the updates for the zone. However, there are cases where certain domain names that should be part of a given zone are delegated to other zones. There may be many reasons for this, including a need to delegate management of a DNS domain to a number of organizations or departments within an organization, or a need to distribute the load of maintaining one large DNS database among multiple name servers to improve the name resolution performance as well as create a DNS fault-tolerant environment. However, this might open up some well defined security issues, such as those associated with what is called "DNS Zone Transfer." Hence, "delegating" management must be carried out with extreme care. At any rate, the above-mentioned NS RRs facilitate delegation by identifying DNS servers for each zone. They appear in all forward and reverse look-up zones. Whenever a DNS server needs to cross a delegation, it will refer to the NS RRs for DNS servers in the target zone. Furthermore, according to Microsoft, if multiple NS records exist for a delegated zone identifying multiple DNS servers available for querying, the Windows 2000 DNS server will be able to select the closest DNS server based on the round trip intervals measured over time for every DNS server.

A number of advanced DNS-management features have been introduced into Windows 2000. Among these is support for AD-based replication. Known also as AD storage and replication integration, in addition to supporting a conventional way of maintaining and replicating DNS zone files, the Microsoft Windows 2000 DNS service has the option of using the AD services as the data storage and replication engine. This way, DNS replication will be performed by the AD service, so there is no need for other support. AD service replication provides per-property replication granularity, and AD service replication is more secure. The reader is urged to take a look at the features of the AD service database. The database is x500 compliant, operates in a tree-like hierarchical manner, and is managed at the domain controller level. The portion of the database that has authorization functions usually resides physically in the same machine that hosts the domain controller. In AD, each resource is identified as an object. Each object can either be a container (which can contain other containers and leaf objects) or a Leaf, that is, a specific resource in the AD tree.

Every object has an attribute that defines its characteristics. Both the classes of object and their attributes are defined in the AD service diagram. Examples of objects contained therein are users, groups, OU (organizational units), and DNS (zone and node). The node contains a DNS record multivalued attribute with an instance of a value for every record associated with the object's name.

Managing Replication and Synchronization Between DNS

As a result of the direct interaction between DNS and AD, all updates affect AD. It is thus AD that deals with record

replication on all the DNSs in a certain domain and subsequently on the other domain controllers. This method is called the multi-master replication model. Particular attention should be paid to the update sequence. This could generate conflicts which are by default resolved in favor of the last one to update. The problem remains of a possibly divergent resolution in the event of a dispute. Practically speaking, the same rule is applied in the case where two or more nodes with the same name are created on two or more DNS servers. Until the conflict is resolved and the DNS server containing an invalid update polls the valid data from the directory service (DS), it is possible that requests for the same object made to two different DNS servers will be resolved differently. This is why the AD service (ADS) database is called loosely consistent.

Managing Zones

The DNS zones can be converted, that is, they can modify their roles. They can transform, for example, from a zone integrated into the DS (AD) to one that is not. Such a modification has to be followed by a series of deletions from AD in order to avoid replicating nonupdated zones. The security of these operations is ensured by secure dynamic DNS updates. The DS maintains the access control lists (ACL) specifying groups or users who are allowed to modify the DS-integrated zones.

This is a principle that is included in the domain name system security extensions (DNSSEC) specifications. In particular, DNS server supports the secure dynamic updates for the DS-integrated zones and Windows 2000 implementation provides even finer granularity allowing per-name ACL specification.

Managing Queries

Here we provide a description of the DNS query procedure. A request of this type is sent by a client (resolver) to a DNS server (a name server), or between two name servers. It is a rather simple process, at least on the conceptual level. A query is merely a request for records of a specified type with a specified name. For example, a query can request all host RRs with a particular name.

There are two types of queries that can be made to a DNS server: recursive and iterative. Some feel that recursive queries inherently compromise performance, especially in distributed environments. A recursive query forces a DNS server to respond to a request with either a fail or success response. Resolvers typically make recursive queries. With a recursive query, the DNS server contacts other DNS servers to help it resolve the request. When it receives a successful response from another DNS server (or servers) it sends a response to the client. Although a recursive query system may have its disadvantages, we cannot simply eliminate it. A recursive query is necessary if a given zone does not contain the requested information. In this case the resolution procedure is delegated to a root DNS, whose information is contained in the cache of every DNS that adheres to the specific RFC. For more information in this regard, visit <http://rs.internic.net/domain/named.cache>.

Iterative queries should be “smarter” than their recursive cousins in that they should be able to provide the best information (also known as referral if the server is not authoritative for the name) based on what the server knows from local zone files or from caching. If a name server does not have any information to answer the query, it simply sends a negative response. Hence there is no interaction with external DNS roots.

Configuring DNS Client

The official Microsoft literature provides an exhaustive description of client configuration, based in any case on a rather common condition: a DNS installed on a domain controller. Granted that this is not the only possible condition, we will begin by describing this scenario. If the server is the first and only domain controller that the administrator installs in the domain, and the server has DNS, the DNS client settings that point to that first server’s IP address should be configured.

Regarding a domain controller with DNS installed, that is, a domain controller that also acts as a DNS server, Microsoft recommends that you configure the domain controller’s DNS client settings according to these specifications: if the server is the first and only domain controller that you install in the domain, and the server runs DNS, the DNS client should be configured to point to that first server’s IP address. DNSs other than the one specified above should not be pointed at by the client.

Furthermore, special attention should be dedicated to the DCPromo process, which promotes or demotes the domain controllers. Granted that in almost all cases a DC/DNS is used together with AD, you have to be careful to concatenate the various DNS servers (and also the various domains) in order to avoid loops and other errors. You can find more information on this at <http://www.microsoft.com/windows2000/techinfo/planning/activedirectory/branchoffice/default.asp>.

On the client side, to check for the availability of the right DNS you first have to key in `ipconfig` to check which DNS the client is pointing at. In particular it will be necessary to set up the DNS registered in AD as the first DNS (if present).

There is also the condition where the domain controller referred to by the client does not have DNS installed. In this case the client will have to point to a DNS having authority over the zone in question, hence, to a local DNS that is RFC compliant. If this is not available, establish a link to a DNS external to your domain but still within the company LAN/ wide area network (WAN). At any rate, Microsoft discourages pointing directly at an external DNS, for example, one on an ISP; it should always be an internal DNS. The same holds for Windows 2000 Server and Windows 2003 Server member servers. It is a different story however if you have servers that are not configured to be part of the domain. In this case you can still configure them to use AD-integrated DNS servers as their primary and secondary DNS servers. If you have nonmember servers in your environment that use AD-integrated DNS, they do not dynamically register their DNS records to a zone that is configured to accept only secure updates (see the verification of authorized DNS

servers mentioned above). Again, according to Microsoft, if you do not use AD-integrated DNS, and you want to configure the nonmember servers for both internal and external DNS resolution, configure the DNS client settings to point to an internal DNS server that forwards to the Internet. Lastly, it may be possible that DNS is needed only to resolve Internet addresses. In this case it will be possible to point directly from the client to an external DNS, for example, that of an ISP.

IMPLEMENTING NAME RESOLUTION BY USING WINS

WINS (Windows Internet Name Service) developed alongside Windows Server systems. WINS provides a distributed database for registering and querying dynamic computer name-to-IP address mapping in a routed network environment.

In Windows 2000 the service was made even more advanced than what had been planned for Windows NT. Its salient features are advanced mapping of NetBIOS addresses, improvement in configurations on the client level, and improvements in management. One of the aspects of this last factor is a distributed database that can handle dynamic queries, also in conjunction with DHCP services to provide easy configuration and administration of Windows-based TCP/IP networks.

One of the most recurrent problems in the previous version of WINS was the resolution of NetBIOS names via IP broadcasts. There was also the need to relieve network administrators of the burden of having to do an excessive number of “manual” operations for updating static mapping files, such as LMHOST files. The WINS implementation under Windows 2000, which is compliant with the NetBIOS Name Server (NBNS) (RFCs 1001/1002), also automatically updates the WINS database when dynamic addressing through DHCP results in new IP addresses for computers that move between subnets. Additionally, the export command can be used to place WINS data into a comma-delimited text file that can be imported into Microsoft Excel, reporting tools, or scripting applications for analysis and reporting.

Under the client side, WINS clients can now re-register without rebooting the server, and they have better fault tolerance because they can query against more than two WINS servers.

The Windows 2000 version of the WINS service has the following new features:

- Persistent connections
- Manual tombstoning
- Improved management tool
- Enhanced filtering and record searching
- Dynamic record deletion and multiselect
- Record verification and version number validation
- Export function
- Increased fault tolerance
- Dynamic re-registration

The most immediate is the improved management system with a graphic user interface (GUI) known as the

Microsoft management console (MMC), which greatly facilitates use. The MMC provides network managers with the consistency of using the console itself for all of their administrative tasks. With MMC, multiple WINS manager windows can be opened at once.

MMC provides better performance thanks to a multi-threaded user interface (UI), which allows background tasks to take place while a foreground task is being performed, providing much faster response. This permits a network manager to run multiple UI tasks simultaneously. A manager can select the active registration node to display the database, and then—rather than waiting for the complete database to be displayed—can select the node of another server, change the configuration of replication partners, or perform other tasks.

It is also possible to use list views. This provides a flexible, Internet Explorer-like function for sorting information according to column type. This means network managers can sort data according to record name, type, IP address, and so on with a simple click of the mouse.

Using PKI for Security Management

Windows 2000 was introduced at a time when public key infrastructures (PKI) had reached a sort of peak and were much touted by vendors—mainly for marketing reasons, as many analysts would comment. Nevertheless we have to take our hats off to the engineers for their farsightedness in coupling Windows 2000 with a real use of public key cryptography.

According to the Redmond Software Producer, like other enabling technologies, public key cryptography requires an infrastructure to deliver its benefits. However, the PKI is not a physical object or software process; instead, it is a set of services provided by a collection of interconnected components. These components work together to provide public key-based security services to applications and users.

Understanding Public Key Cryptography

Public key cryptography differs from single key cryptography by the use of two separate keys, one of which can be—or rather must be—distributed publicly. There are a number of well known PK cryptographic algorithms. Some, such as RSA (Rivest-Shamir-Adleman) and ECC (elliptic curve cryptography), are general purpose in the sense they can support many security operations. Below we mention a few of them that are used massively by Windows 2000 PKI.

One of the most common (and important) aspects of public key cryptography is that of creating and validating digital signatures. This is based on a mathematical transform that combines the private key with the data to be “signed” to such that only someone possessing the private key could have created the digital signature. Anyone with access to the corresponding public key can verify the digital signature. Any modification to the signed data (even changing only a single bit in a large file) invalidates the digital signature. Digital signatures are themselves just data, so they can be transported. The use of digital signatures can be further improved by the use of authentication,

by means of which it is possible to authenticate keys and their possessors by verifying the credentials given to the public keys. This attribution of “identity” is otherwise accomplished via the attribution of a digital certificate, which are what the PKIs are based on.

Certificates provide a mechanism for gaining confidence in the relationship between a public key and the entity owning the corresponding private key. A certificate is a particular type of digitally signed statement; the subject of the certificate is a particular subject public key and the certificate is signed by its issuer (holding another pair of private and public keys). Typically, certificates also contain other information related to the subject public key, such as identity information about the entity that has access to the corresponding private key. Thus, when issuing a certificate the issuer is attesting to the validity of the binding between the subject public key and the subject identity information.

Certificates are created, managed, and validated by a certification authority (CA), an entity often having legal status that deals with validating the match between the real and the virtual entity (the latter accompanied by keys and certificates). The CAs are hierarchical and may refer back to root systems called root CA.

Managing Clients

Windows 2000 clients are fundamentally interoperable with the PKIs. To tell the truth they already were way back in days of Windows NT 4.0, Windows 98, and Windows 95. At any rate, one of the most important characteristics of the implementation under Windows 2000 is integration with the domain administration and policy model, which dramatically simplifies application management within the enterprise.

With Windows 2000 it becomes simpler to generate and manage keys for one or more PK algorithms. Microsoft's CryptoAPI supports installable cryptographic service providers (CSP) supporting key generation and management for a variety of cryptographic algorithms. The CryptoAPI defines standard interfaces for generating and managing keys that are the same for all CSPs.

Keys can be stored in a number of ways. Mechanisms for storing key material are dependent on the selected CSP. The Microsoft-provided software CSPs (or base CSPs) store key material in an encrypted form on a per-user or per-machine basis. Other CSPs may implement different mechanisms. For example, smart card CSPs store the public-key pair in the smart card tamper-resistant hardware and generally require entry of a PIN code to access operations involving the private key. These “protection” mechanisms are transparent to an application, which references all key pairs via a key-set name unique in the context of a CSP. This is a rather important feature which, especially in the current historical time-frame, is used a great deal by banks.

We mentioned certification authorities above. Practically speaking, the PKIs under Windows 2000 are able to manage Microsoft or third party PKIs; they just need to be compatible with the standard. Microsoft also reminds us that support for PKCS-10 and PKCS-7 messages is provided by a Microsoft-supplied enrollment control

(Xenroll.dll) which can be scripted for Web-based enrollment or called programmatically to support other transport mechanisms such as RPC, DCOM, and e-mail. This control allows the calling application to specify the attributes included in the PKCS-10 message and allows use of an existing key pair or generation of a new key pair.

The PKI supports multiple enrollment methods including Web-based enrollment, an enrollment wizard, and policy-driven “auto-enrollment,” which occurs as part of a user’s logon processing. Subsequently, Microsoft decided to evolve the certificate enrollment process in a manner consistent with the certificate request syntax (CRS) document created in the IETF PKIX working group.

Certificates can be renewed. Certificate renewal is conceptually similar to enrollment, but takes advantage of the trust relationship inherent in an existing certificate. Renewal assumes the requesting entity wants a new certificate with the same attributes as an existing, valid certificate, but with extended validity dates. A renewal may use the existing public key or a new public key.

Renewal is of advantage primarily to the CA. A renewal request can presumably be processed more efficiently since one need not re-verify the existing certificate attributes. Renewal is currently supported in the Windows 2000 PKI for automatically enrolled certificates. For other mechanisms, a renewal is treated as a new enrollment request.

Industry-standard message protocols for certificate renewal are not overall accepted, but are included in the IETF PKIX CRS standards.

MORE SECURITY WITH IPSEC

One of a server’s most important defensive tools against outside attacks is the use of access control devices (switches, routers, and firewalls) that should be configured to block all undesired traffic to the TCP and UDP ports corresponding to the network services that cannot, for whatever reason or choice, be deactivated. Furthermore, beyond issues related to the installation and configuration of these devices, it is always wise, especially when hardening a Web server, to implement additional connection filtering policies, even on the single host level. This ensures the presence of an extra layer of security which may help if one of the perimeter control devices ends up being bypassed by an attacker. The Windows 2000 operating system offers two tools for the implementation of connection filters: TCP/IP filters and IPsec filters.

TCP/IP Filters

This function is identical to the one in the Windows NT 4 operating system and it can be accessed via the properties menu of the local network connection by selecting Internet Protocol (TCP/IP) | Properties | Advanced | Options | TCP/IP Filtering | Properties.

In spite of the apparent benefits of filtering on the TCP/IP level, there are a number of drawbacks:

The rules created are applied in a monolithic fashion to all network cards

New settings have no effect whatsoever on existing connections and require a system reboot

There are a few functional problems: specifically, the filters appear not to fully comprehend the IP portion relating to the type of protocol (for example, although only TCP traffic corresponding to protocol number 6 is allowed, ICMP traffic will still not be blocked)

The filters can only be managed at the local level, which means more work for the administrator

The lack of granularity in connection control makes the tool rather inflexible and poorly suited to real use

The use of these functions is thus discouraged for these and other reasons, not least of which is the fact that more flexible tools are now available such as IPsec filters.

IPSec Filters

IPsec filters represent one of the advantages deriving from Windows 2000’s full support for the IPsec protocol. IP Security is an extension of the IP protocol (it is an option with IPv4 and native with IPv6) defined by the Internet Engineering Task Force (IETF) (RFC 2401-2411) and aimed at resolving the natural insecurity of IP-based networks through a nucleus of integrated services guaranteeing authentication, integrity control, and traffic confidence by using well known cryptographic algorithms. In addition to these, IPsec also offers “minor” functions, including the possibility of defining filtering rules for single host connections. The Windows 2000 components that ensure support for IPsec are IPsec policy agent and IPsec driver. The former is a bona fide system service that acquires policies as they are developed and distributes them to the various mechanisms. The latter is a driver that is loaded during system bootup and it is responsible for filter operation and connection maintenance. The driver thus directly uses the defined filters to determine which packets have to be blocked and which are acceptable.

IPsec filters have a series of advantageous characteristics such as:

Speed and efficiency in processing received datagrams

The possibility of being applied at individual network interfaces

Sufficient specificity in the type of managed and recognized protocols

Immediate operativity without system reboot

Creating Policies

The whole IPsec mechanism revolves around the concept of policies. A policy is an abstraction, a sort of virtual container that assembles various types of rules. These rules may encompass one or more lists of filters, each of which is assigned specific actions (e.g., accept or block). The first step in creating filters is the definition of a new policy. Proceed as follows:

Right click on IP Security Policies on Local Machine, which you can find via Programs | Administrative Tools | Local Security Settings.

Select the menu item Create IP Security Policy and follow the wizard. Give a name to the policy (for example, Web Server Security) and write a brief description.

In the next window, uncheck the Activate the default response rule box, click Next, leave the Edit box active, click Finish, and close the next properties window that pops up automatically.

Creating Filters

After having created a new policy and given it a name, you need to associate it with the appropriate list of filters.

Right click on IP Security Policies on Local Machine in the Local Security Settings window and select the menu item Manage IP filter lists and filter actions.

In the next window click Add from the Manage IP Filter Lists tab and give a name and brief description to the new list (e.g., Web server consented traffic).

Then click the Add button and add two new filters that will allow, for example, TCP connections only through the Web server ports 80 (http) and 443 (https).

We do not have to define a specific action for this list because it should already exist at the system level (and if we go to the Manage filter actions tab we should notice an action called Permit).

Proceeding in a similar fashion we also have to create a list of filters to block all nonconsented traffic (calling it, for example, Web Server Non-Consented Traffic). For this list we have to define a preset action as follows:

Select the Manage filter actions tab, unselect the Use Add Wizard box and click on the Add button.

In the next window, select Block in the Security Methods tab, give a name to the type of block (for example, Web Traffic Block) in the General tab and close the window by clicking OK.

Associating Filters and the Policy

Once the policy and the various list of filters with their associated actions have been determined, you will have to link them together. Here's how to do it:

Right click on the new policy in the Local Security Settings window and choose Properties.

In the next window unselect the Use Add Wizard checkbox and click on the Add button.

Then, on the Manage IP filters tab, select the list of access filters and go to the Manage filter actions tab.

Select Permit and close the window by clicking OK.

Do the same thing to associate the block-traffic list with its associated action.

Assigning the Policy to a Network Interface

The last step in making the whole mechanism operative is to assign the policy to a network interface (in the case of a Web server with two network cards, this would naturally be the public interface).

In the properties window of the specific local network connection, select Internet Protocol (TCP/IP) | Properties.

On the General tab, click Advanced and go to the Options tab.

Select IP filter | Properties, activate Use following rules and select the previously created policy from the list.

This way the filters become immediately operative without having to reboot the system.

THE TCP/IP STACK IN WINDOWS 2000

The TCP/IP stack in the Microsoft Windows 2000 family of operating systems introduces a number of improvements with respect to earlier implementations, including:

- Increase in default size of TCP windows and the introduction of new algorithms to improve high congestion and high delay connections as well as the overall performance of the stack

- Full compliance with RFC 1323 regarding scalable TCP window size

- Full support for the selective acknowledgements (SACK) mechanism

- A fast TCP packet retransmission mechanism

- Improvements in round trip time (RTT) and retransmission timeout (RTO) algorithms

- Improvements in management of a large number of connections

Furthermore, support is also guaranteed for other characteristics such as Internet protocol security (IPSEC), network address translation (NAT), quality of service (QoS), layer tunneling protocol (L2TP), and others.

Stack Security Parameters

The suite of TCP/IP protocols in Windows 2000 gets all the information for their proper function from the system registry to which they are written by the installation program and, in certain cases, by the DHCP client service, if used. Generally the default settings are good enough for a large variety of environments. However, in some circumstances (for example, in the case of a Web server) it may be opportune to manually reconfigure certain parameters to improve the robustness of the TCP/IP stack and the overall level of security.

However, modifications made manually to the system registry can make the whole system unstable. So before you go monkeying around, you should back up all your data and also the configuration registry. It is also strongly recommended to verify the new setup on test systems before replicating any modification on "working" systems.

Thanks to the management experience acquired by the Win2000test.com laboratories, Microsoft has succeeded in adding to the configuration registry a set of keys that can be set to "calibrated" settings to increase system resistance especially regarding certain types of attacks (e.g., denial of service). The parameters in question are found under the registry key.

HKEY_LOCAL_MACHINESYSTEMCurrentControlSet\Services\Tcpip\Parameters and are the following:

SynAttackProtect (REG_DWORD—valid settings: 0,1,2): the correct setup of this key reduces the attempts to

retransmit SYN-ACK signals, reducing the time that the resources associated with the connections have to remain allocated. In order for this protection mechanism to operate effectively the maximum set values for the `TcpMaxHalfOpen` and `TcpMaxHalfOpenRetried` keys have to be exceeded. The default setting for the key is 0 (no protection) but a value of 2 is generally recommended. This offers the best protection because resource allocation is delayed until the three-way handshake has been completed. Nevertheless, this setting may at times cause connectivity problems especially for users who use remote connections with long response times. You should also remember that when the key is set to 2, certain stack functions cannot be used (specifically the scalable windows mechanism, window size, and the initial RTT);

`TcpMaxHalfOpen` (REG_DWORD—valid settings: 100 - 0xFFFF): this sets the maximum number of connections in the SYN_RCVD-permitted state before the `SynAttackProtect` key protection kicks in (the default value is 100 for the Windows 2000 Professional and Server systems and 500 for Advanced Server systems). The most opportune value depends on the environment but even more so on the volume of traffic that the server normally has to handle;

`TcpMaxHalfOpenRetried` (REG_DWORD—valid settings: 80 - 0xFFFF): this sets the maximum number of connections in the SYN_RCVD state for which there has been at least one retransmission of a SYN-permitted signal before the `SynAttackProtect` key protection kicks in (the default value is 80 for the Windows 2000 Professional and Server systems and 400 for Advanced Server systems). Here too, the most opportune value depends on the environment but even more so on the volume of traffic that the server normally has to handle;

`EnablePMTUDiscovery` (REG_DWORD—Boolean - valid settings: 0,1): this parameter affects the behavior of the TCP/IP stack in determining the maximum transmission unit (MTU), that is, the maximum size of network packets. A default value of 1 limits their size to a previously selected value. This translates into a lower probability of packet fragmentation by routers along the pathway with a lower MTU value. In spite of the advantages deriving from this setting, a value of 0 (false) is generally recommended because a fixed value of 576 bytes is used for all connections not directed to local network hosts, thus blocking all attempts to force the MTU down to low values to overload the stack;

`EnableDeadGWDetect` (REG_DWORD—Boolean - valid settings: 0,1): when this parameter is set to 1 (default) the TCP stack is able to use the “dead gateway” recognition function. With this mechanism, when a connection through the default gateway sends a TCP packet without received a response from the target for a certain number of times (half the value set for the `TcpMaxDataRetransmission` key) the routing path cache is overwritten so as to set up a secondary gateway for this connection provided that it has been defined in the network setup. The recommended setting for the key is 0 because this prevents an attacker from forcing connections to go through undesired gateways;

`KeepAliveTime` (REG_DWORD—valid settings: 1 - 0xFFFFFFFF): this parameter indicates the frequency (in

milliseconds) of the attempts with which the stack verifies that an inactive connection is still established by sending a keep-alive packet. The default value is 7,200,000 milliseconds (2 hours), but a setting of 300,000 (5 minutes) is recommended.

There are also two other system registry keys that have an influence on network security. One of them is located on the pathway

HKEY_LOCAL_MACHINESYSTEMCurrentControlSet-
Services TcpipParametersInterfaces <interface no.>:

`PerformRouterDiscovery` (REG_DWORD—valid settings: 0,1,2): this parameter monitors whether the operating system attempts to detect the router applying RFC 1256. The recommended value is 0 because this prevents attempted attacks based on creating a counterfeit router. The default value is generally 2 if a DHCP service is used, or else 0,

whereas the other is found under

HKEY_LOCAL_MACHINESYSTEMCurrentControlSet-
Services NetBTPParametersInterfaces <interface no.>:

`NoNameReleaseOnDemand` (REG_DWORD—Boolean - valid settings: 0,1): this parameter specifies whether the machine releases its NetBIOS name when it receives a name-release request from the network. The default setting is 0, whereas a setting of 1 is recommended, because this protects against attacks that try to get the name (Microsoft Security Bulletin MS00-047). However, you should bear in mind that this setting may have no effect at all for a network interface where the NetBIOS/SMB/CIFS services have been disabled (as it should be for the external network interface of a Web server).

Preliminary Remarks About Windows 2000 Server Remote Access

The Windows 2000 Server remote access, which is part of the integrated routing and remote access service, makes it possible to connect remote or mobile users to the networks of organizations. Remote users can work as if their computers were physically connected to the network.

The users run the remote access software and send a connection to the remote access server. The remote access server, which is a computer running Windows 2000 Server and the routing and remote access service, authenticates the user sessions and services until they are closed by the user or the network administrator. All services generally available to users connected to a LAN, such as file and printer sharing, access to the Web server, or messaging, are activated via the remote access connection.

The remote access clients use standard tools to access resources. A computer running Windows 2000 allows clients to use file manager to connect to storage devices and printers. The connections are permanent. Users do not have to re-establish connections to network resources during the remote access sessions. Given that the drive

letters and the universal name convention (UNC) names are supported by remote access, most applications on the market, even when customized, run without need for any modifications.

A remote access server running Windows 2000 provides two different kinds of remote access connectivity:

Remote connection. This is established when a remote access client makes a nonpermanent remote access connection to a physical port on a remote access server using a telecommunications provider service, for example an analog telephone line or ISDN. The best example of remote connection is a remote connection client who dials the telephone number of one of the remote access server ports. A remote connection on an analog or ISDN telephone line is represented by a direct physical connection between the remote connection server and the client. Data sent over the connection can be encrypted even though it is not a virtual private network (VPN).

Virtual private network (VPN). A VPN comprises protected point-to-point connections through a private or public network such as the Internet. A VPN client uses special TCP/IP protocols known as tunneling protocols to make a virtual call to a virtual port on a VPN server. The best example of a VPN is a VPN client who makes a VPN connection to a remote access server connected to the Internet. The remote access server responds to the virtual call, authenticates the caller, and transfers data between the VPN client and the company network.

Unlike remote connection, the VPN is always an indirect logical connection between the VPN client and the VPN server. In order to guarantee privacy, the data sent over the connection have to be encrypted.

Remote Access Functions in Windows 2000 Server

Remote access under the Windows 2000 server offers a number of new functions:

Integration with Windows 2000 AD. A remote access server running Windows 2000 and part of a Windows 2000 domain registered in AD can access the user remote access settings memorized in AD, such as remote access authorizations and recall options. Once the server is registered in AD, it is possible to display and manage the contents of the remote access server using AD-based tools such as routing and remote access.

MS-CHAP version 2. Microsoft challenge handshake authentication protocol (MS-CHAP) version 2 significantly increases protection for transfer of protection credentials and for the generation of encryption keys during the negotiation of a remote access connection. MS-CHAP version 2 is specifically designed to authenticate VPN connections.

Extensible authentication protocol (EAP). With EAP it is possible to use new authentication methods with remote access. This is an important feature especially for the distribution of protection based on smart cards. EAP represents the interface that allows other authentication

modules to connect to the Windows 2000 remote access PPP implementation. Windows 2000 supports EAP-MD5 CHAP, EAP-TLS (used for smart cards and authentication based on certificates), and the transmission of EAP messages to a RADIUS server.

Bandwidth allocation protocol (BAP). Thanks to BAP and bandwidth allocation control protocol (BACP), the multilink PPP protocol is made more efficient with the addition or deletion (depending on the case) of additional connections for managing changes in traffic flow. BAP is useful especially for operations where the number of simultaneous lines is based on the use of bandwidth. In Windows 2000 the BAP criteria can be set via remote access criteria. For example, a network administrator can set up a system so that a supplemental line will be cut off if use of the connection falls below 50% for more than 10 seconds. BAP offers a very effective mechanism for controlling connection costs while seeking the optimal bandwidth.

Remote access criteria. These criteria represent a series of connection settings that provide greater flexibility to network administrators in setting up remote access authorizations and connection attributes. Remote access criteria allow administrators to authorize incoming calls on the basis of date and time, the remote connection user's Windows 2000 group, or requested connection type, including remote connection or virtual private connection. Connection settings include limitations on maximum session time, authentication and encryption type, BAP criteria, and IP packet filtering.

RADIUS client. The Windows 2000 remote access server can act as a remote authentication dial-on user service (RADIUS) client on a RADIUS server. Windows 2000 provides RADIUS server functions through the Internet authentication service (IAS). An IAS server can offer authentication, authorization, and centralized accounting functions, as well as a central position for setting remote access criteria.

Layer two tunneling protocol (L2TP). In addition to the point-to-point tunneling protocol (PPTP), a remote access server running Windows 2000 includes the industrial standard layer two tunneling protocol (L2TP), which is used together with the IPsec to create protected VPN connections.

Support for AppleTalk Macintosh remote access clients. Windows 2000 remote access now supports the remote connections of Apple Macintosh remote access clients who use the AppleTalk protocol together with the point-to-point protocol (PPP).

IP multicast support. Thanks to the use of the Windows 2000 IGMP routing protocol, a remote access server can relay IP multicast traffic between connected remote access clients and the Internet or company network.

Account blocking. This is a protection function that blocks access after a set number of failed authentication attempts. Account blocking is designed to help prevent illicit connection attempts. By this we mean when an unauthorized user attempts to connect using an unknown username and a list of common words as passwords. Account blocking is disabled in the default setting.

Operations Improving Remote Access Management

Here is an important list of operations to carry out to ensure correct implementation and configuration of the remote access server:

Use DHCP to obtain IP addresses. If a DHCP server is installed, set up the remote access server so that DHCP is used to obtain IP addresses for remote access clients. If no DHCP server is installed, set up the remote access server with a static IP address pool that contains a subset of addresses from a subnet to which the remote access server is connected.

Use detailed authentication.

Do not use passwords based on names or words. Use advanced passwords that are more than eight characters long and that contain a combination of uppercase and lowercase letters, numbers, and acceptable punctuation. This prevents unauthorized users from hitting on the right passwords by sending commonly used names or words.

Even though the EAP-TLS protocol functions with certificates based on the system registry, for security reasons it is advisable to use EAP-TLS with smart cards.

If you are using MS-CHAP, use the version 2. You can request from Microsoft the most updated version of MS-CHAP for Windows NT version 4.0, Windows 98, or Windows 95, or for remote access clients running Windows NT.

Use automatic IPX network ID allocation.

Configure the remote access server so that the same IPX network ID is automatically allocated to all remote access clients.

Avoid setting up different remote access criteria for the same user.

If a user makes an incoming call using a multiple connection, all the connections must be made using the same remote access criterion as the first connection.

A Number of Detailed Procedures for Enabling the Routing and Remote Access Service

The routing service of Microsoft Windows 2000 Server offers multiprotocol routing services: LAN-to-LAN, LAN-to-WAN, VPN, and network address translation (NAT). Windows 2000 Server routing should be used by system administrators who are familiar with routing protocols and services, as well as with routable protocols such as TCP/IP, IPX, and AppleTalk.

You have to have administrator access to install and set up the Windows 2000 router. But first all the necessary hardware has to be installed correctly:

LAN or WAN card with a certified NDIS (network driver interface specification).

One or more compatible modems and a free COM port.

A multiport card to achieve adequate performance in multiple remote connections.

An ISDN card (if you use an ISDN line).

Check the Microsoft Windows Hardware Compatibility List on the Microsoft Web site to verify the compatibility of the hardware components of a computer running Windows 2000 Server.

Before proceeding with the installation and configuration of this complex of services, you should make sure you have done the following:

For a new network, decide which routing characteristics and protocols for the Windows 2000 router you want to use. For an existing network, determine which routing characteristics and protocols for the Windows 2000 router have to be activated.

Install and configure the protocols.

Activate and configure the routing and remote access service.

(Optional) Develop and distribute static IP routing.

(Optional) Develop and distribute the RIP routing protocol for IP.

(Optional) Add and configure the DHCP relay agent.

(Optional) Configure IP multicast support.

(Optional) Develop and distribute network address translation (NAT).

(Optional) Configure the appropriate IP or IPX packet filters.¹

(Optional) Develop and distribute on-demand routing.

If you are not a domain administrator and if the server is a member of the Windows 2000 Active Directory domain, the domain administrator will have to add the server computer account to the RAS and IAS server security group in the server's domain. The domain administrator can add the computer account to the RAS and IAS server security group using users and computers in AD or else by using the command `netsh ras add registered server`.

Open Routing and Remote Access.

In the default setting, the local computer is listed as a server.

To add another server, right click on server status in the console, then choose add server.

In the add server dialog box, click the applicable option and then hit OK.

In the console, right click on the server you want to enable and then select configure and enable routing and remote access.

Follow the instructions in the routing and remote access wizard.

Note: To open routing and remote access, click on Start, choose Programs, then Administrative Tools, and then Routing and Remote Access.

Addition and Removal of Routing Protocols

To add an IP routing protocol

Open Routing and Remote Access.

In the console select General.

¹ IPX and SPX are very rarely used anymore; we have mentioned them here for the sake of completeness.

Pathway

Routing and Remote Access

Server name

IP Routing

General

Right click on General, then choose New routing protocol.

In the Routing protocols box, select the protocol you want to add, then hit OK.

If necessary, complete the configuration dialog windows for the protocol.

Note: To open Routing and Remote Access, click on Start, choose Programs, then Administrative Tools, and then Routing and Remote Access.

To delete an IP routing protocol.

Open Routing and Remote Access

In the console select an IP routing protocol.

Pathway:

Routing and Remote Access

server name

IP Routing

IP routing protocol

Right click on the IP routing protocol you want to eliminate and then choose delete.

Note: To open Routing and Remote Access, click on Start, choose Programs, then Administrative Tools, and then Routing and Remote Access.

Static Route Management

To add a static route

Open Routing and Remote Access.

In the console, select Static routes.

Pathway

Routing and Remote Access

server name

IP Routing or IPX Routing

Static Routes

Right click on Static routes, then do one of the following:

For a static IP route, click on New static route.

For a static IPX route, click on New Route.

In the Static route dialog box do one of the following:

For a static IP route, in the Interface, Destination, Network mask, Gateway, and Metric boxes, enter the interface, the destination, the network mask, the gateway, and the metric. If it is an on-demand connection interface, the Gateway box will not be available. You will also be able to select Use this route for on-demand connections for on-demand call-up connections for traffic on the route.

For a static IPX route, in Network number (hexadecimal), Next MAC hop Address (hexadecimal), Tick count, Hop count and Interface, enter the network number, the next MAC hop address, the tick count, the hop count, and the interface.

Note: To open Routing and Remote Access, click on Start, choose Programs, then Administrative Tools, and then Routing and Remote Access.

To delete a static route

Open Routing and Remote Access.

In the console select Static routes.

Pathway

Routing and Remote Access

server name

IP Routing or IPX Routing

Static routes

In the details box right click on the static route that you want to delete and then choose Delete.

You can also perform operations on default static IP routes.

To add a default static IP route

Open Routing and Remote Access.

In the console select Static routes.

Pathway

Routing and Remote Access

server name

IP Routing

Static routes

Right click on Static routes, then choose New static route.

In the Interface box, choose the interface that you want to use for the default route.

In the Destination box type 0.0.0.0.

In the Network mask box type 0.0.0.0.

In the Gateway box do one of the following:

If it is an on-demand connection interface, Gateway is not available. Select Use this route for on-demand connections for on-demand call-up connections for traffic on the route.

If the interface for this route is a LAN connection such as Ethernet or Token Ring, type in the IP address of the router interface on the same network segment as the LAN interface.

In the Metric box, type 1.

THE USE OF NAT FOR "SHARED" INTERNET CONNECTIONS

With the network address translation in Windows 2000 it is possible to configure the home or small business network so as to share a single connection to the Internet. NAT includes the following components:

Translation component

The NAT-enabled Windows 2000 router, henceforth called "NAT computer," functions as a network address translator, translating the IP addresses and the TCP/UDP port numbers of packets relayed between the private network and the Internet.

Addressing component

The NAT computer provides configuration information of the IP addresses to other computers in the private network. The addressing component is a simplified DHCP server that assigns an IP address, a subnet mask, a default gateway, the IP address of a DNS server, and the IP address of a WINS server. In order to automatically receive the IP configuration, the computers in the private network have to be configured as DHCP clients. The TCP/IP configuration of computers running Windows 2000, Windows NT, Windows 98, and Windows 95 is analogous to a DHCP client.

Name resolution component

The NAT computer becomes the DNS server and the WINS server for the other computers in the private network. When the NAT computer receives name resolution requests, it relays those requests to the DNS and WINS servers on the Internet for which it is configured, and returns the responses to the computer in the private network.

In planning this sort of implementation, please bear in mind the following: because NAT includes an addressing component and a name resolution component provided by the DHCP, WINS, and DNS services to the hosts on the private network, it is not possible to use the DHCP service or the DHCP relay agent if NAT addressing is enabled or the DNS service if NAT TCP/IP network name resolution is enabled.

How NAT Works in Practical Terms

If a network ID 10.10.0.0 is used for the intranet of a small company and if the use of the public address w1.x1.y1.z1 was granted by the Internet service provider (ISP), all the private addresses on 192.168.0.0 will be translated into the IP address w1.x1.y1.z1 by NAT. If several private addresses are translated into the same public address, NAT will use certain TCP and UDP ports in a dynamic fashion to distinguish one intranet position from another.

The addresses w1.x1.y1.z1 and w2.x2.y2.z2 represent the valid public IP addresses allocated by the Internet network information center (InterNIC) or by an ISP.

In the following illustration we have an example of using NAT to connect an intranet to the Internet in a transparent fashion.

If a private user at the address 10.10.0.10 uses a Web browser to connect to the Web server at the address w2.x2.y2.z2, an IP packet containing the following information will be created on the user's computer:

Destination IP address: w2.x2.y2.z2

Origin IP address: 10.10.0.10

Destination port: TCP 80

Origin port: TCP 1025

This IP packet is then sent to the NAT protocol, which translates the outgoing packet addresses into the following information:

Destination IP address: w2.x2.y2.z2

Origin IP address: w1.x1.y1.z1

Destination port: TCP 80

Origin port: TCP 5000

The NAT protocol keeps the mapping between the address {10.10.0.10, TCP 1025} and the address {w1.x1.y1.z1, TCP 5000} in a table.

The translated IP packet is sent via Internet. The response is sent back to the origin and received by the NAT protocol. The arriving packet contains the following public address information:

Destination IP address: w1.x1.y1.z1

Origin IP address: w2.x2.y2.z2

Destination port: TCP 5000

Origin port: TCP 80

The NAT protocol checks the translation table, maps the public addresses to the private ones and relays the packets to the computer whose address is 10.10.0.10. The relayed packet contains the following address information:

Destination IP address: 10.10.0.10

Origin IP address: w2.x2.y2.z2

Destination port: TCP 1025

Origin port: TCP 80

For outbound packets from the NAT protocol, the origin IP address (private address) is translated to the address allocated by the ISP (public address), and the TCP/UDP port numbers are translated to different TCP/UDP port numbers.

For inbound packets to the NAT protocol, the destination IP address (public address) is translated to the original intranet address (private address), and the TCP/UDP port numbers are translated to the original TCP/UDP port.

It should be pointed out that packets that contain the IP address only in the IP heading are translated appropriately by NAT. Packets that contain the IP address in the IP payload may not be translated correctly by NAT.

An important function is also provided by the Windows 2000 NAT Editor. The normal translation of network addresses is based on the translation of the following elements:

The IP addresses in the IP heading.

The TCP port numbers in the TCP heading.

The UDP port numbers in the UDP heading.

Any translation of elements other than the above requires additional processing and additional software components called NAT editors. A NAT editor modifies the IP packet beyond just translating the IP address in the IP heading, the TCP port in the TCP heading, and the UDP port in the UDP heading.

HTTP (hypertext transfer protocol) traffic on the Internet does not need, for example, a NAT editor because this type of traffic implies only the translation of

the IP address in the IP heading and the TCP port in the TCP heading.

Below we illustrate two situations where NAT editors are required:

The IP address, the TCP port, or the UDP port is memorized in the payload.

The file transfer protocol (FTP) memorizes, for example, the numerical representation of the IP addresses in the FTP heading for the PORT FTP command. If NAT does not correctly translate the IP address in the FTP heading and regulate the flow of data, there may be connectivity problems.

The TCP or UDP port will not be used to identify the data flow.

Data using the point-to-point tunneling protocol (PPTP) do not use a TCP or UDP heading. Instead they use a generic routing encapsulation (GRE), and the tunnel ID memorized in that heading identifies the flow of data. If NAT does not correctly translate the IP tunnel in the GRE heading, there may be connectivity problems.

NAT editors are integrated into Windows 2000 for the following protocols:

- FTP
- ICMP
- PPTP
- NetBIOS on TCP/IP

The NAT routing protocol also includes proxy software for the following protocols:

- H.323
- Direct Play
- LDAP-based ILS
- RPC

We remind you that it is not possible to manage IPsec under Windows 2000 with the incorporated NAT editor.

Using IIS: From the Installation to the Administration

The information provided in this section refers to IIS version 5.0. For information on later versions of IIS, consult the documentation provided with the setup program.

Internet information services (IIS) 5.0 is installed by default with Windows 2000 Server. You can remove IIS or add new components using Add/Remove Programs in the control panel.

To Install IIS

Click Start, Settings, Control Panel, and then double click on Add/Remove Programs.

Select Add/Remove Windows Components, then the Components button, and then follow the instructions of installing, removing, or adding components to IIS.

NB:

If you upgrade to Windows 2000, IIS 5.0 will be installed with the default settings only if it was already installed on the previous version of Windows.

Software Checklist

Before you install IIS make sure the following are installed on your computer:

TCP/IP protocol and Windows connectivity utilities. If information is published on the Internet, your ISP will provide the IP address of the server, the subnet mask, and the IP address of the default gateway. The default gateway is the ISP computer through which your computer's exchanges with the Internet are routed.

We also recommend installing the following optional components:

The DNS service should be installed on a computer in the intranet. If your intranet is small you can use the hosts or Lmhosts files on all the computers in the network. Although it is optional, this allows users to use names in text format instead of IP addresses. Internet sites often use the DNS service. To connect to a site that is registered under a domain name, users can enter the domain name into the browser.

For security reasons, Microsoft recommends NTFS formatting of all the units used with IIS.

Microsoft FrontPage to create or edit HTML pages of a Web site. FrontPage is a what-you-see-is-what-you-get (WYSIWYG) editor with a user-friendly graphic user interface (GUI) for operations such as inserting tables, graphics, or text.

Microsoft Visual InterDev to create and develop interactive Web applications.

Related Notes

If IIS is already installed, you can get additional information from the online IIS documentation by typing <http://localhost/iisHelp/> into your browser's address bar and hitting return.

Complete IIS documentation is available at <http://windows.microsoft.com/windows2000/en/server/iis/>.

Troubleshooting

If you have problems with the Web server, use the information provided in this section to resolve the problems described below.

Installation check

Once installation has been completed, you can check that it was done correctly using Internet Explorer to view the files in the home directory.

To check the installation of a Web site on the Internet

Make sure there are HTML files in the wwwroot folder of the Web server.

Start a Web browser, such as Internet Explorer, on a computer with an active Internet connection. You can do this on the computer you are checking, but it is preferable to use another computer in the network.

Type in the URL of the home directory of the new Web site.

The URL will be composed of "http://" followed by the name of the Web site, followed in turn by the pathway of the file you want to see. Please note the use of the slash. If your site is registered in DNS as "examples.microsoft.

com” and you want to view the file homepage.htm, which is located in the main directory of the home directory, type the following into the address bar: `http://examples.microsoft.com/homepage.htm` and hit return. You will see the home page.

To check the installation of a Web site on an intranet

Make sure the computer you are using has an active network connection and that the WINS server service is running or some other name resolution method.

Launch a Web browser such as Microsoft Internet Explorer.

Type in the URL of the home directory of the new server. The URL will be composed of “http://” followed by the name of the server on the Windows network, followed in turn by the pathway of the file you want to see. Please note the use of the slash. If your site is registered in the WINS server as “Admin1” and you want to see the file homepage.htm, which is located in the main directory of the home directory, type the following into the address bar: `http://admin1/homepage.htm` and hit return. You will see the home page.

Related Topics

If IIS is already installed, you can get additional information from the online IIS documentation by typing `http://localhost/iisHelp/` into your browser’s address bar and hitting return. Complete IIS documentation is available at `http://windows.microsoft.com/windows2000/it/server/iis/`.

At any rate, IIS is currently one of the most widely used Web servers. The Version 5.0 has been substantially reworked architecturally to the point where it has become a closely integrated component of Windows 2000 Advanced Server, Server, and—albeit with some limitations—Professional OS.

The main consequence of such a great success is that this system has drawn special attention from hackers and is thus very sensitive in terms of information security.

In this section we will look at aspects regarding the installation, configuration, and administration of IIS 5.0, dedicating particular attention to precautions to use in order to ensure an adequate level of security for the system.

In addition to the WWW service, other standard services generally associated with the IIS server include FTP, SMTP, and NNTP, and others that we will not be dealing with in this article, such as certificate server, index server, and Microsoft transaction server. Taken together, these services constitute a complete and integrated platform for e-business applications.

IIS: More Tips About Installation

It is a common (and misguided) notion that information security consists solely in the implementation of suitable measures to protect against external attacks. Actually it is impossible to know with any certainty or precision what it is you have to protect yourself against and what means you should use to do so unless you have carefully analyzed the situation, something which is of great help in avoiding poor choices that you will later rue.

The same is true, albeit in modified form, for the installation of software components, in particular those that may have an impact on the intrinsic security of an operating system such as a Web server. To simplify matters, we have listed below the steps to take in order to install IIS 5.0 correctly:

Carefully read the “Windows 2000 Security Guide” and the documentation provided with the server. You cannot expect to make a system secure without first finding out all you can about it. If this is the first installation it might not even be a bad idea to do a trial installation;

Carefully review the security policies regarding the file-system, the configuration registry, password management, user rights, and all other aspects that have a direct or indirect relation with system security;

Review the documentation on all vulnerabilities that have affected IIS 5 in the past and download the patches provided by Microsoft;

Make sure the hardware on which IIS will be installed is truly adequate for the criticality of the service. This means computing power (CPU, RAM), data safeguarding (backup systems, RAID), and service continuity (UPS, clusters). After having resolved these issues, you will have to decide where to install your Web server;

Do not overlook the logistics aspects, which also have to be correlated to the criticality of the service. As a rule, it is preferable to have a temperature-controlled room with a fire protection system and limited access in order to exclude nonauthorized persons;

Choose the most suitable OS configuration. This means using servers configured in standalone mode that are not part of a Windows 2000 domain and that thus do not have trusted relations with other servers. This precaution helps prevent certain types of attacks based on privilege escalation or on exploiting trust;

In addition to the WWW and perhaps the FTP services, only run the other services that are truly necessary (link to the service configuration section);

Make sure that IP routing has been disabled to prevent undesired access to the intranet from the Internet and remove at the operating system level all protocols that are not absolutely necessary, with the sole exception of TCP/IP;

If you install IIS on a system that is directly accessible from the Internet, block all incoming traffic with a firewall or router and enable traffic again only after completing the configuration. This trick is very important since before all the necessary defenses have been set up, the server could be easily compromised.

IIS: Configuration and Administration

After you have installed the system you will have to perform the initial configuration and then administer it once it is up and running. In this case as well for clarity of exposition we will describe the steps to follow to render secure a standard installation of IIS 5.0:

Configure the user for the anonymous access created automatically during installation. The name is usually

IUSR_computername where the computer name is the name of the machine hosting IIS. This user has to have the minimum possible privilege level. You also have to make sure that on the properties tab the checkboxes User Cannot Change Password and Password Never Expires are ticked. Furthermore, the account has to be a local user and not require rights such as access this computer from network or log on as a batch job. If the Web site does not contemplate allowing anonymous access the best thing to do is to disable the IUSR_computername account;

Create at least two new groups of users to use with IIS. The first group will include users with system administrator functions. If the server handles a number of Web sites and/or services (WWW, FTP, etc.) it will be necessary to create an administrative account for each site or service. The second group will include users with nonadministrative privileges and will be the one held in consideration for the definition of NTFS authorization. In any case, the user IUSR_computername has to be associated exclusively with the second group and thus removed from the guest group, to which it is associated automatically by default;

Disable via the administration control panel the default site created during the installation. This operation has to be done not for the WWW service, but also for all of the others (FTP, SMTP, NNTP);

Create, using the wizard, a new site that is different from the default site. Here you will have to choose the name, IP address, and the listening port, and define the root directory which should preferably reside in a partition different from that accommodating the operating system.

It is also important that the minimal access level be set for this directory;

Edit the authorizations regarding the installation directory so that neither the everyone and guests groups nor the guest account have access privileges. Do not forget that after installation the everyone group automatically has full control privileges to the default home directory (for example C:\Inetpub) and this could lead to the situation where the users in this group are used as vehicles for unwanted access;

Delete or move all directories containing example scripts that are generally installed automatically (even though there is an option not to install the examples). Although access to the examples is limited to the loopback address (localhost – 127.0.0.1), it is still preferable to delete or move the specified directories. If you should choose not to adopt this solution, then opportune authorizations have to be imposed that are only granted to administrative users. Table 2 presents the recommended authorizations for the various IIS directories.

Configure the auditing functions necessary for proper system monitoring. IIS memorizes all HTTP/FTP/SMTP events in incoming and outgoing server traffic while a general – logging—which cannot be extended – logging—is offered for the NNTP service.

Carefully choose the type of data to register in the log files so that important information may be obtained by examining them:

a series of failed commands executed in sequence
attempts to download/upload particular files from/to
directories containing executables

Table 2: Recommended Authorizations for the Various IIS Directories

Type	Example Directory	Example Data	NTFS Authorizations	IIS 5 Authorizations
Static content	Inetpubwwwroot Inetpubwwwrootimages Inetpubftprootftpfiles	HTML, images, download FTP	Administrators (Full Control); System (Full Control); WebAdmins (Read & Execute, Write, Modify); Authenticated Users (Read & Execute); Anonymous (Read & Execute);	Read
FTP upload	Inetpubftprootdropbox	Directory used as a place for users to store documents for review prior to the Admin making them available to everyone	Administrators (Full Control); WebAdmins or FTPAdmins (Read & Execute, Write, Modify); Specified Users (Write)	Write
Script	Inetpubwwwrootscripts	.asp	Administrators (Full Control); System (Full Control); WebAdmins(Read & Execute, Write, Modify); Anonymous (Read & Execute)	Read & Script
Other executables and include files	Inetpubwwwroot executables Inetpubwwwrootinclude files	.exe, .dll, .cmd, .pl .inc, .shtml, .shtm	Administrators (Full Control); System (Full Control);	Read & Scripts, Executables

attempts to access internal files with the extension .bat or .cmd

requests coming from an identical IP address with characteristics indicating attempts at a Denial of Service (DoS) attack

Logging is enabled by default but you should still:

Change the pathway and name of the log file to hamper any attempts at altering it to mask illicit activities

Allow complete access to the log file directory only to administrative users

Monitor via Windows 2000 auditing the following types of events: Create Files / Write Data, Create Folders / Append Data, Delete Subfolders and Files, Delete, Change Permissions, or Take Ownership, which have their critical aspects for a Web server

Develop opportune log rotation rules on the basis of real needs (for example, a new file each day). It might also be useful to extend the information memorized in the file using the Extended Logging Properties function.

Delete all ISAPI extensions that are not strictly necessary. The mechanism provided by these extension is particularly powerful and flexible since it acts in such a way that different Web resources are managed in a completely transparent manner using different applications (in practice these are dll libraries or dynamic connections). However, in certain cases these applications have revealed specific vulnerabilities (buffer overflows). Hence, when they have no real use it is recommended to disable the associated extension in order to nip those risks in the bud. The Table 3 contains a list of typical ISAPI extensions in IIS with information on their field of application.

Download and use the tools available on the Microsoft Web site that may be helpful during the IIS configuration and/or startup phase (iisperm, hisecweb.inf, iislock).

BACKUP

Every information system is characterized by information having varying degrees of sensitivity. The nature of

these data obviously varies depending on the role of the system, but nevertheless their importance implies the need to deploy suitable measures to prevent any harm from coming to them, and—and since there are no 100% guarantees in this respect—to allow them to be restored quickly if anything does happen so as to prevent negative consequences, be they economic or legal, or simply a question of image.

To this end, planned periodic backup procedures allow administrators easily to cope with all those situations, whatever the reason or nature (virus, hardware failure, malicious attacks), when an immediate recovery of data is necessary.

Naturally, for a backup policy to be truly effective it has to be well designed and engineered with respect to the system that is being protected.

In this section we will address the salient aspects of this theme, examining at some length the tool ntbackup available with the Windows 2000 operating system.

Identifying Data

The first concrete necessity is to identify which data you are going to protect by means of backup. It would be inconceivable to back up every disk on the server every time you perform a backup, and hence the data especially requiring protection have to be singled out (for a Web server, as in our case, a considerable part of these data are the html pages, the scripts, and everything else that is part of the server resources). Additionally, but at greater time intervals, it is also a good idea to take a snapshot of the state of the system (startup and configuration files, configuration registry), and to create an emergency boot disk to be used should the system ever be unable to boot up on its own.

Choice of Support

The choice of support for backing up data will depend on the quantity of data to be copied and on the length of time that they will need to be kept. Fortunately there is currently a vast range of products on the market with prices and characteristics to satisfy a great variety of requirements. The most important thing is to make a decision keeping in mind not only your needs but also all aspects related to security (for example, opt for removable supports that can be kept in a safe place and/or write-once-read-many supports that are intrinsically more secure).

Scheduling

The time intervals between the data backup operations have to be calibrated on the basis of concrete needs, the speed at which the saved data are modified, and their importance.

Using ntBackup

This operating system utility meets data copying and restoration needs in a more than satisfactory fashion either using its GUI or through commands on the prompt line (although with some limitations in this latter case). Although there are certainly more sophisticated software

Table 3: List of Typical ISAPI Extensions in IIS with Information on Their Field of Application

Extension Type	Function
.htr	Web Password Reset
.idc	Internet Database Connector
.stm,.shtm,.shtml	Server Side Include
.printer	Internet printing
.cer	Represents a certificate
.cdx	Active Channel File Definition
.asa	Active Server Application
.htw,.ida,.idq	Index Server

products on the market, the ability to rely on an application already integrated into the operating system is nothing to turn your nose up at. Essentially, the application allows you to carry out the following operations:

- Backup of files or directories on removable or non-removable supports
- Data restore
- Backup of data regarding system state
- Restoration of data regarding system state
- Creation of an emergency boot disk

To back up files or folders you have to be the owner with authorization to read, read/run, or edit, or be a local system administrator or backup operator. Clearly the best thing to do from the security standpoint is to create a special user and assign it to the backup operators. It is also a good idea to limit access to the backup files by ticking the checkbox Owner or administrator backup data access only in the dialog box Information on backup process.

Backing Up Your Data

To run backup using the graphic user interface you will have to:

- Select the files, directories, and drives to be backed up
- Select the backup support or pathway
- Select the options
- Launch the process or else schedule it for a later time

There are five different types of backup to choose from:

normal: A normal backup copies all selected files and marks each file as having been backed up (in other words, the archive attribute is cleared). With normal backups, you need only the most recent copy of the backup file or tape to restore all of the files. You usually perform a normal backup the first time you create a backup set;

copy: A copy backup copies all selected files but does not mark each file as having been backed up (in other words, the archive attribute is not cleared). Copying is useful if you want to back up files between normal and incremental backups because copying does not affect these other backup operations;

daily: A daily backup copies all selected files that have been modified the day the daily backup is performed. The backed-up files are not marked as having been backed up (in other words, the archive attribute is not cleared);

differential: A differential backup copies files created or changed since the last normal or incremental backup. It does not mark files as having been backed up (in other words, the archive attribute is not cleared). If you are performing a combination of normal and differential backups, restoring files and folders requires that you have the last normal as well as the last differential backup;

incremental: An incremental backup backs up only those files created or changed since the last normal or incremental backup. It marks files as having been backed up (in other words, the archive attribute is cleared). If you

use a combination of normal and incremental backups, you will need to have the last normal backup set as well as all incremental backup sets in order to restore your data;

The combination of normal and incremental backup requires a minimum amount of memory and is thus the fastest method. However, because backup data can be archived on different disks or tapes, the restore operation is relatively complex and time consuming. Conversely, the combination of normal and differential backup takes longer, especially if the data are frequently modified, but it is easier to restore the data since the backup set resides on just a few disks or tapes.

Restoring Data

In order to restore data you will need to:

- Select the files you want to restore from the catalog
- Select the destination for the files and/or folders
- Select the options
- Launch the restore process
- Use the command line

The utility `ntbackup` can be run from the command prompt or a batch file without having to use the graphic interface but this involves two principal limitations:

- You can only back up entire folders and not single files. You can get around this by indicating a `.bks` file containing a complete list of files to back up (however, you will need to use the GUI to create the `.bks` file)

- Wildcard characters are not supported

A complete list of the command line parameters can be found in the online guide.

HARDENING AND SECURITY MEASURES

Mechanisms that make it possible to identify changes at the filesystem level may be considered an integral part of any self-respecting security strategy. The reason is very simple. When a host is compromised by a malicious attack, one of the first things that the attacker does is to install "trojanized" versions of a number of important system executables, edit essential configuration files, or install other programs to open back doors in the system.

In this section we will examine the function of one of the best-known tools for verifying the integrity of the filesystem. It is known as Tripwire, and here we will be looking at version 2.2.1 for Windows NT/2000.

Tripwire was originally developed for the UNIX platform by Gene Kim and Eugene Spafford in the early 1990s but was later adapted to other platforms. The software is sold commercially by Tripwire Inc. (<http://www.tripwire.com> or <http://www.tripwiresecurity.com>).

Tripwire is a fully fledged member of the host-based intrusion detection systems (HIDS) because it is normally installed on the host it is supposed to protect. It focuses on the filesystem and not on network connections or the TCP/IP layer.

The application acquires a snapshot of the files selected for monitoring and catalogs them by getting a digital fingerprint for each. The fingerprint is a one-way hash that allows Tripwire to detect changes to any of the files at any time.

When changes occur that do not correspond to particular conditions, these changes are reported to the administrator in various ways (reports, email). The administrator can then confirm the changes, updating the internal signatures database, or else realize that they are unauthorized modifications and seek to restore the previous situation.

Installing Tripwire

There are no particular difficulties in installing the software because it is sold in the form of an archive with its own setup procedure.

During the setup process the user is asked to make choices regarding the configuration, which can be modified at any point. Most importantly, the user is asked to specify a “passphrase” that the software will use to digitally sign the files used by the application.

Function of Tripwire

Tripwire uses an architecture based on a set of files, each of which performs a specific task:

Policy file: this contains a series of rules specifying which elements of the filesystem and Windows registry to monitor, the data that have to be collected for each of them, and perhaps the email address for notification of any suspicious activity

Database files: Together, these represent the snapshot of the system. Obviously this snapshot has to be taken when you are 100% sure about the integrity of the system. Every time there is a system integrity check, this snapshot is compared with the current state of the objects in order to highlight all the possible differences or changes

Report files: these contain the information deriving from a check of filesystem integrity and display any anomalies found

Configuration file: this contains specific information for Tripwire operations and is initially written during the setup procedure

Key files: these files contain the public and private keys used to encrypt the files used by the application in order to prevent them from being modified in undesired ways. The keys, in turn, are encrypted by means of a secret passphrase

Before beginning it is absolutely necessary to modify the policies file. Here you can look at the file twpol.txt, which is installed with the software and contains a set of rather general rules.

The policies file has to be edited using any text editor so that its rules will be specific to the needs of the server to be protected (consult the exhaustive online manual for an explanation of the meaning of the various rule properties and attributes). The modifications can be saved in another text file (with a well-chosen name) and has to

be digitally signed and installed as the new policies file before initializing the internal database. In order to do this you have to open a prompt window and type in the following command: `twadmin --create-polfile <name of policies text file>`

The new file will be installed in the folder indicated as the destination in the configuration file. After this it is possible to initialize the internal database by typing the command: `tripwire --init-verbose`

A signatures database will then be created in the folder indicated by the DBFILE variable in the configuration file.

Database Integrity Checks and Updates

Given the importance of the filesystem, it is opportune that its integrity be checked on a regular basis. The scheduling will depend on the real needs, but as a rule of thumb, a daily check is advisable to prevent any unpleasant surprises. The process can be launched in a prompt window (or using a batch file) with the following command: “`tripwire --check`”

With this instruction, the software checks the integrity of the filesystem on the basis of the specially created policies. It prints to screen a list of any anomalies and saves a copy of the report in binary format in the folder indicated by the variable REPORTFILE in the configuration file. It is also possible to carry out checks rule by rule, or by severity level of the anomalies, or for a specific section of the policies file (check the user’s manual).

If and when anomalies are found, the internal database has to be updated so that it reflects the current state of the system and so that “normal” modifications will not be reported in the future as critical situations: “`tripwire --update --twrfile <name of file report>`”

The database can also be updated immediately after the check when the check is initiated by the command: “`tripwire --check --interactive`”

Synchronization has to be carried out in the event of changes to the policies file when:

It is necessary to add new objects to the list of monitored system components;

It is necessary to modify the rules because they are causing too many false positives;

You want to change the recipient of the email notifications or the way the rules are grouped;

In all these cases you have to take the following steps:

Create an ASCII version of the policies file via the command `twadmin --print-polfile > <name of text file>`

Edit the text file as desired

Instruct the software to accommodate the modifications via the command `tripwire --update-policy <name of text file>`

As a default setting the update process is carried out with a high level of security level in that it launches a simultaneous integrity check according to the new rules and displays any violation of old policy rules that is also covered by the new rules. Since the database is not updated if anomalies are found you have to make sure that the reported events are in fact normal, and if so, proceed with

the update launching the process at a low security level via the command: `tripwire --update-policy --secure-mode low <name of the policies text file>`

FORENSIC ACQUISITION UTILITIES

Although security is not the main topic in this chapter, we might mention here some free utilities for carrying out initial incident response procedures in the event of an attack. The forensic acquisition utilities (FAUs) are a collection of utilities and libraries to manage digital investigations in a Windows environment. These utilities are widely used in information security to sterilize media for forensic duplication, discovering the position of logical volume information, verifying evidence integrity, and so forth. FAU should be used with a hardware write blocker. These utilities represent a very useful set of tools that includes the most up-to-date versions of the most widely used open-source digital forensics utilities.

FAU is available from the Web site <http://users.erols.com/gmgarner/forensics/> and includes a modified version of Ulrich Drepper's MD5 checksum implementation in Windows DLL format. FAU is compatible with Windows 2000 and subsequent versions of Windows.

CONCLUSION

In this chapter we have sought to blend a high level description of the Windows 2000 operating system with some introductory technical guidelines and tips for people who have had to reckon, willingly or unwillingly, with the world of Windows. The platform is still widely used and deserves a bit of attention, even though on the formal level, Microsoft's support for this system is being phased out. But there are still so many sites based on Windows 2000 that it is almost impossible to avoid them. Our goal here has been to provide a number of basic operational guidelines to ensure the correct use of this operating system and to lay out the groundwork for the development of a new platform.

GLOSSARY

Active directory (AD): Active directory is Microsoft's trademarked directory service, an integral part of the Windows 2000 architecture.

Digital signature: An electronic signature that can be used to authenticate the identity of the sender of a message or the signer of a document, and possibly to ensure that the original content of the message or document that has been sent is unchanged.

DNS SECurity: A set of extensions to the DNS system that are designed to prevent attacks against the DNS system as well as DNS hijacking, which directs the user to an erroneous Web site. DNSSEC uses a digital signature to ensure that the correct IP address is used. For more information, visit www.dnssec.org.

Dynamic host configuration protocol (DHCP): A consolidated standard that greatly simplifies administration of networks based on TCP/IP protocols.

Elliptical curve cryptography (ECC): A public-key encryption technique based on elliptic curve theory that can be used to create faster, smaller, and more efficient cryptographic keys.

Fault tolerance: The ability of a system or component to continue normal operation despite the presence of hardware or software faults.

Multithreading: Multitasking within a single program. It allows multiple streams of execution to take place concurrently within the same program, each stream processing a different transaction or message. In order for a multithreaded program to achieve true performance gains, it must be run in a multitasking or multiprocessing environment, which allows multiple operations to take place.

NetBIOS: An acronym for Network Basic Input/Output System. The NetBIOS API allows applications on separate computers to communicate over a local area network. In modern networks, it normally runs over TCP/IP (NBT), giving each computer in the network both a NetBIOS name and an IP address corresponding to a (possibly different) host name. Older operating systems ran NetBIOS over NetBEUI. NetBIOS provides services related to the session layer of the OSI model.

Partitioning: The purpose of partitioning is to create a logical file structure for the operating system to access and to divide a portion of the disk drive to be used by more than one disk operating system.

PKI (public key infrastructure): A framework for creating a secure method for exchanging information based on public-key cryptography.

Tombstoning: Refers to a discrete component (resistor, capacitor) that has turned straight up instead of laying flat as it goes through the soldering process. It can be caused by uneven amounts of soldering paste at different ends of the component or by shadows on the board causing different temperatures at the ends.

WINS: Windows Internet Naming Service (WINS) is Microsoft's implementation of NetBIOS name server (NBNS) on Windows, a name server and service for NetBIOS computer names.

INTRODUCTION

Linux is a free operating system (OS) originated by Linus Torvalds (cf. http://en.wikipedia.org/wiki/Linus_Torvalds) and further developed by thousands of others interested in the success of the free operating system. Although Linus originally contributed the initial kernel for what has become known as the Linux OS, he has overseen the continued development of the kernel, as well as the growth of what has become known as the Linux OS, often referred to simply as Linux. Linux benefits from the inclusion of free software from other sources, including most notably GNU software provided by Richard Stallman's Free Software Foundation (FSF). So although Linus originally contributed the kernel and still manages it, all the supporting standard Unix utilities (such as grep, tar, emacs, make, sed, and most notably the C compiler and symbolic debugger) are provided by the FSF. The graphical user interface for Linux, known as X Windows, is currently provided by the X.Org Foundation. The Linux OS is an open-source system developed under the GNU Public License, which stipulates that the source code may be freely copied and compiled, with the only stipulation that one cannot at any point take away the free right to copy, and any additions to the source also become public and freely available under the GNU License. Begun in 1991, Linux has grown from the interest of a very few highly-focused software developers to an industrial-strength OS deployed on millions of computers, from small portable devices to large mainframes.

HISTORICAL CONTEXT: UNIX OPERATING SYSTEMS PRIOR TO LINUX

AT&T Unix

Ken Thompson and his associates at AT&T Bell Labs delivered the first release of their Unix OS in November of 1971. The Unix OS was one of the world's first multiuser, multiprocessing operating systems, meaning that multiple users could be logged on to the same computer each running different programs, and the operating system could handle the load efficiently either by swapping the various users' programs onto a single processor, very

quickly so that it would appear that the users' programs were actually running at the same time (a strategy known as "task swapping").

Because AT&T was prohibited from engaging in any business activity that did not directly deal with the delivery of phone service as a result of an antitrust decree handed down in the 1950s to AT&T and Western Electric Company, it decided to license the source code of its new Unix operating system to educational institutions for a minimal licensing fee (as low as 50 dollars). The power and flexibility of Unix made it an immediate hit, and the fact that the source code was easily available meant that the user community could contribute to the ongoing development of the operating system, by submitting bug fixes and enhancements back to AT&T Bell Labs for their incorporation.

In the fall of 1975, Ken Thompson, Unix's original creator (along with several others, including Rudd Canaday and Dennis Ritchie) was invited to visit the University of California, Berkeley, and offer a course in operating systems. He brought Unix along with him to demonstrate. Several individuals at Berkeley were impressed (many had already been using various versions of Unix by that time), and Ken helped to port one of the releases of Unix over onto Berkeley's Digital Equipment Company PDP computer (the PDP 11/70). One of Ken Thompson's students at Berkeley was Bill Joy, who ported Unix to DEC's new computer, the VAX 11/780. The versions of Unix developed at Berkeley under Bill Joy's direction came to be known as BSD Unix, which stood for Berkeley Software Distribution. BSD Unix came to be an important alternative to AT&T Unix.

Prior to 1976, Unix computers were stand-alone, meaning that they were not networked, although multiple users could be logged into the computer at the same time. This changed when Mike Lesk of AT&T developed a program called UUCP (for Unix to Unix Copy), which allowed two Unix computers that were networked together to be able to copy files back and forth between them.

Another important late 1970s event took place in 1978, when Eric Schmidt, working at Berkeley on his master's thesis, developed a networking program for BSD Unix that he called "Berknet," which allowed up to 26 different Unix

computers to be interconnected together over a network. Berknet provided numerous capabilities including file transfer as well as email. By 1983, partly through the funding support of the U.S. Department of Defense Advanced Research Projects Agency (DARPA), Berkeley BSD version 4.2 was released in September of 1983 and supported the Berkeley socket interface. The Berkeley socket interface has since been adopted as the backbone of the Internet, and is supported by all networked computers, including Microsoft Windows OS as well as, of course, Linux (Stevens, 1990).

The Unix Divorce

By the late 1970s, AT&T realized that it had a valuable product in Unix, but the 1956 antitrust decision still prohibited AT&T from profiting from it. However, in 1982 AT&T was forced by another antitrust decision to dissolve into multiple “Baby Bells.” The immediate effect of this dissolution of AT&T was that Unix now for the first time was considered intellectual property owned by AT&T, and no one was allowed to publish the source code in any form. Now, instead of being able to obtain Unix (along with the source code for modification) for a licensing fee under 100 dollars, corporations had to pay license prices skyrocketed in 1993 to sums as high as 200,000 dollars for a single source license (Salus, 1994, 222). AT&T threatened to sue any individual or organization that infringed on its copyright and it did so. Individuals as well as some institutions could no longer afford to license Unix on the scale and with the freedom that they had been able to previously. BSD Unix had also gone commercial in the form of Sun Microsystems’s SunOS (Sun was started by former Berkeley student Bill Joy). Eventually other companies started selling their own versions of Unix, including IBM (AIX), Hewlett-Packard (HPUX), Silicon Graphics (IRIX), and Digital Equipment Corporation (Digital Unix). There were dozens of other offerings as well.

Richard Stallman and the GNU Project

The commercialization of Unix prompted outrage and resentment in the academic world, because students had become used to having a wonderful platform on which to develop and work, not to mention the creative opportunities to work together to enhance a “community” OS effort. One of the individuals severely bothered by the commercialization of Unix was an MIT researcher by the name of Richard Stallman. In 1984, Stallman responded by creating the Free Software Foundation (FSF) and the GNU Public License (GPL). “GNU” is a recursive anagram for “GNU is Not Unix”—indicating that Unix had by that time become a “four-letter-word.” The GPL was designed, unlike most copyright licenses, not to prohibit reuse of licensed software, but rather, precisely to perpetually protect the free use of the licensed software, so that it would forever be free and no one could revoke that freedom and claim it as proprietary by not releasing source code along with binary code. This does not mean that software released under the GPL becomes “public domain,” but rather that any software obtained under the GPL can be freely copied, compiled, used, republished, and cannot at any point in the future be made

proprietary. Code under the GPL must always remain free and available as source code—it cannot be redistributed purely as binary code. Stallman began an effort to create Unix-like software and publish it under the GPL. Central to this effort was the creation of the GNU C compiler, a number of core Unix utilities, and a user interface or shell known as Bash (Bourne Again Shell—a play on words of the original Unix shell written by Stephen Bourne at AT&T, known simply as “sh”). A goal of the GNU effort was to create a truly free Unix-based operating system, which Stallman dubbed GNU Hurd. The development of Hurd began in earnest in 1990. It was and is a microkernel-based operating system (see the discussion of Minix below) based mainly on the CMU (Carnegie Mellon University) Mach code base now known as gnumach. Mach helps to form the core of several Unix-like operating systems, including Hurd as well as Apple’s popular MAC OS X operating system.

Early development of Hurd was slow, partially because of Mach’s complexity and partly because of licensing issues related to Carnegie Mellon University and the release of Mach under the GPL. Although discussions about Hurd had been progressing for over five years, there was still no operational GNU operating system as the 1980s ended and the 1990s began. There was a vacuum begging to be filled.

Minix

In 1987 Andrew Tanenbaum, an American by birth teaching in Amsterdam, Netherlands, at the Vrije Universiteit, published a book titled *Operating Systems: Design and Implementation*. A large part of the book is dedicated to the discussion of a microkernel, a concept that incarnates Antoine de St. Exupery’s idea that perfection is achieved not when there is nothing left to add, but rather, when there is nothing left to take away. A microkernel is a minimalist operating system kernel that provides only the most basic of system services, such as memory and thread management, along with basic interprocess communication. All other common operating system features, such as device drivers, file management, networking, and so on are delivered as modules (called “servers”) that run as any other user program on top of the microkernel. The advantages of a microkernel include the ability to “plug and play” different filesystems, devices, networking services, and so on, without burdening the core operating system kernel with the overhead. A “monolithic” kernel, on the other hand, incorporates many services into the kernel itself, thus making the kernel itself larger but also faster and easier to manage and develop. In order to elucidate the concepts of microkernels in his textbook, Tanenbaum included in an appendix the source code for a Unix-based microkernel implementation that he called (punning on the minimalist concepts of microkernels) “minix.”

During his undergraduate studies at the University of Helsinki, Linus Torvalds studied Tanenbaum’s textbook and started playing with the ideas and the code. The problem was that Minix (at the time) could not be altered by the public—in the sense that no one but Tanenbaum himself was allowed to make changes to the source code and then redistribute those changes. This lack of freedom is

primarily what prompted Linus to begin, in April of 1991, to write the basics of a new operating system kernel. The initial development of the kernel which eventually came to be known as “Linux” (Linus had originally wanted to call it “freax”) was done using the GNU C compiler running on Minix. Other factors that enabled Linux to succeed include an effort initiated by the Institute of Electrical and Electronics Engineers (IEEE) to form a committee in 1986 to define a formal standard for Unix-based operating systems, to try and regain some compatibility among a multitude of competing Unix systems. This standard was called POSIX, which stands for portable operating systems interface based on Unix.

Another critical success factor for the success of Linux was an announcement by AT&T, in 1987, to purchase shares in Sun Microsystems, which resulted in a powerful marriage between the BSD and AT&T versions. The first major result of this new relationship was the integration of SVR3 and 4BSD into a new operating system offering from Sun, called Solaris. The second result of this marriage between AT&T and Sun was the creation of the Open Software Foundation (OSF), a group formed by the “other” Unix vendors, who did not want to be left out in the cold. This group included Digital, IBM, and Hewlett-Packard, among others. Without the POSIX and OSF efforts it is doubtful that Linux (or any other Unix operating system) would have had the success that it has had (Tanenbaum, 2001).

LINUX DEVELOPMENT

The Early Years: 1991–1995

On August 25th, 1991, Linus Torvalds posted a now-famous post on the Usenix newsgroup comp.os.minix

(<http://groups.google.com/group/comp.os.minix/msg/b813d52cbc5a044b?output=gplain>). It read:

```

Hello everybody out there using minix -

I'm doing a (free) operating system (just a hobby,
won't be big and
professional like gnu) for 386(486) AT clones.
This has been brewing

since april, and is starting to get ready. I'd like
any feedback on

things people like/dislike in minix, as my OS re-
sembles it somewhat

(same physical layout of the file-system (due to
practical reasons)

among other things).

I've currently ported bash(1.08) and gcc(1.40),
and things seem to work.

This implies that I'll get something practical
within a few months, and

I'd like to know what features most people would
want. Any suggestions

are welcome, but I won't promise I'll implement
them :-)
```

Linus (torva...@kruuna.helsinki.fi)

PS. Yes - it's free of any minix code, and it has a multi-threaded fs.

It is NOT protable [sic] (uses 386 task switching etc), and it probably never

will support anything other than AT-harddisks, as that's all I have :-).

The interesting thing to note here is that in the four months between April and August of 1991, Linus had created, from scratch, a “minix-lookalike” kernel that was capable of running the GNU C compiler. In September of 1991, version 0.01 of Linux was released, which included over 10,000 lines of code. It also sported the GNU bash shell (Bourne Again Shell). People rushed to compile the entire GNU FSF corpus of utilities onto the new Linux kernel. Thus Linux grew substantially by standing on the shoulders of existing code provided by the FSF and others.

At this early stage, Linux had no networking capability, ran only on an Intel 80386 processor, and had limited support for external devices such as tape drives. The early 1991 releases of Linux still required Minix to compile the system, and used a Minix filesystem (which had significant restrictions—including 14-character filename and 64 megabyte filesystem limits). Early Linux was not a stand-alone system, in the sense that it could be built and installed by itself. This changed with the December 1991 release of Linux 0.11, the first stand-alone version of Linux in the sense that it could be compiled under itself. In January of 1992 postings about Linux were no longer going to the comp.os.minix newsgroup. Instead, they were going to alt.os.linux, with the comp.os.linux newsgroup being created later in March of that year.

Two things principally distinguished this fledgling operating system from its Minix predecessor. First, the kernel was a monolithic kernel rather than a microkernel like Minix. Second, Linux was soon released under the GPL, which made it “free” for modification and republication as long as any new enhancements were also released under the GPL. Another thing that distinguished Linux from Minix was release 0.95 in March of 1992. This was the first release that supported the X Windows graphical interface. This was a huge step forward in the acceptance of Linux, as it promised for the first time the ability to run a windowing interface on top of the text-based shell. In contrast, Minix did not add X Windows support until 14 years later, in the 3.1.2 version of Minix that was released in March of 2006.

For the next two years, Linux hovered at various minor releases of 0.99, slowly growing in capability and extent and size. The first official release of Linux 1.0.0, in March of 1994, marked the growth of the code base to 17 times its original size, partly as a result of the inclusion of TCP/IP networking and Berkeley sockets into the kernel. Also included in the 1.0 release was support for multiple filesystems, SCSI storage devices, and running IP over a network (for modem-based network connections). It was also at this time that the versioning patterns for Linux were created. Kernels with odd-numbered minor releases (1.1, 1.3, 1.5) were designated as developer-targeted kernels, whereas kernels with even-numbered minor releases (1.0, 1.2, 1.4, 1.6) were designated as stable user-targeted

kernels suitable for inclusion into released distributions. By the kernel 1.2 release in March of 1995, one year after the release of 1.0, Linux's size had almost doubled once again to over 175,000 lines of code. Along with the 1.2 release was the beginning of the move from a strict Intel-only platform, with code becoming available for Sparc-, Alpha-, and MIPS-based systems. Along with each new release came significantly increased capabilities. In June of 1996, Linux 2.0 was released, which included a fully functional 64-bit implementation for the Alpha and support for multiprocessor-based systems. Improvements were also delivered to memory management, TCP/IP networking, kernel threads, and support for loadable modules.

Since 1991, over 10,000 individuals across the world have contributed in some way or another to the development of Linux, either to the kernel itself or its myriad utilities and supporting environments. There are an estimated 20 to 30 million users of Linux throughout the world. Much of the reason for this is the development of easy to install packages, or distributions, that have been made available over the years. A distribution combines a default release of the Linux kernel, along with X Windows, graphical environments including Gnome and KDE, packaged into an easily installed and configured installation, complete with versioning of existing components. The first major advance in this distribution effort was made by Patrick Volkerding who released a packaging of Linux he called Slackware on July 16th, 1993. Other distributions followed on as companies provided copies of source trees on CDs. These included Yggdrasil and Walnut Creek. Today, there are over a hundred Linux distributions. The most recognized include SUSE Linux, Mandrake Linux, Debian Linux and Gentoo Linux, and RedHat, some of which are backed by public corporations. As an example of the extraordinary development effort that went into Linux during its first three years of existence, at the 1994 Comdex Conference on computing in Las Vegas, the staff of Yggdrasil demonstrated an example of the Windows game Solitaire running on a Linux system under WINE (the Windows Emulator for Linux) (cf. <http://www.linuxjournal.com/article/0045>).

In March of 1994, *The Linux Journal*, the premier journal devoted to all things Linux, began publication. It featured a comparison of Linux and OS2 in its first issue, and included an interview with Linus Torvalds. Over the past 12 years, *The Linux Journal*, along with other print magazines and online magazines, including *Linux Magazine* and *Linux Gazette* (an online publication that began in July of 1995), have aided in communicating information for Linux users across the world. In addition to journals, Matt Welsh, who originally managed the Linux Documentation Project (<http://www.tldp.org/>), wrote (with Lar Kaufman) one of the first books published on Linux in 1995 titled *Running Linux*.

The Open-Source Revolution

The powerful combination of the already-existing GNU tools and compilers, combined in 1991 with a GPL-based operating system kernel in the form of Linux, catapulted the adoption of free software into the fast lane. Although throughout the 1990s Linux was just catching on, by the late 1990s it had proven itself a viable free platform, and

with a couple of other key successes in the open-source world, such as the Apache Web Server, which accounted for almost 70 percent of the Web server market by 2000, and by 2000 was running almost one-third of the world's Internet servers (<http://www.leb.net/hzo/ioscount/>). A 2004 *Information Week* survey found that roughly 67 percent of the companies questioned use open source or free software products, with an additional 16 percent planning to begin using it by 2005, and only 17 percent of those polled having little or no intention of incorporating open-source products into their environments over the near future (cf. <http://www.informationweek.com/story/showArticle.jhtml?articleID=51201599&tid=5979>). Although most successful open-source products, including Sendmail, PHP, OpenSSH, MySQL, to name a few, are not dependent on Linux, all these open-source products run on Linux and other Unix variants. The success of Linux has had a fundamental legitimizing effect in the further worldwide corporate adoption of other open-source products.

Linux in the 21st Century

As of August 21, 2006, Linux was 15 years old. In Internet years, that's a long time. Linux is still firmly grounded in its original philosophy as interpreted by Linus Torvalds and based in fundamental Unix principles. Linux development continues through the efforts of thousands of individuals who volunteer and provide their time and resources in order to improve "their" operating system. Today, the Linux kernel (2.6.17) has 6.9 million lines of code supporting close to two dozen different target architectures. As new hardware devices come into the market, new device drivers are written for the drivers and are incorporated into the Linux kernel. When Linus began developing Linux in 1991, he did not have to worry about high-speed networks, USB flash drives, wireless networks, or Bluetooth devices. As these and other new technologies have come into play, new Linux drivers have been written to support them. Linux continues to grow as a solid operating platform based on the sound fundamental principles that gave it its birth.

Today, Linux has the support of numerous major corporations, including IBM, Hewlett Packard, Sun, and almost every major corporation with the exception of Microsoft. Commercial and open-source databases targeting Linux include Oracle, DB2, MySQL, Sybase, Informix, PostgreSQL, Ingres, to name a few, almost every major DBMS in the world, with the exception of Microsoft SQL Server. Development environments supporting the GNU development tools are highly available as well. Whether Linux can sustain itself amidst all this growth in interest in terms of support, and keep its core integrity in terms of reliability, is yet to be seen.

OPERATING SYSTEM STRUCTURE

Fundamental Structure

The structure of Linux resembles other Unix-like OS (for more detailed information on Unix structure, see Shacklette 2004). This includes the typical Unix hierarchical filesystem, files and directories and permissions on each, hard and symbolic file links, individual user accounts and home directory, login processing and security, an online help

system in the form of “man,” pipes and filters, fundamental utilities such as ls, tar, cp, mv, etc., common editors including vi and emacs, and the notion of a user interface known as a shell, which itself supports redirection, command history, aliases, functions, job control, shell scripts and variables, along with command line editing and completion. Anyone with experience on any other Unix-like system will feel perfectly at home on a Linux system. Berkeley-derivative users, such as those who might have used Digital Unix or any of the BSD variants, might find the filesystem naming convention different, or the system startup process different from what they are used to (Linux uses System V init), or might find certain commands different in terms of their options (e.g., ps). But by-and-large, any Unix user will feel perfectly at home on a Linux system.

Figure 1 shows a screenshot of a typical Linux system running on an IBM Thinkpad laptop:

Again, with Mozilla Firefox, Gimp, Emacs, Smalltalk, and a Terminal, this screen looks familiar to any Unix user.

The Linux operating system supports the fundamentals of Unix philosophy, namely, using small utility programs that are designed to do one thing and do them well. It also supports the idea that these small utility programs,

known as “filters,” should be able to be “strung” together to form pipelines, so that data can be moved from one to the other in a stream, and each program can act as a filter to modulate or transform the data in one way or another. Unix requires a common text data format in order for these pipelines to function, and Linux as a Unix system supports text as its fundamental data format.

As an example of a pipeline, let’s take the Unix utility echo, which is a standard Unix utility that “echoes” the contents of a file or stream of data to the screen. Another utility, named gawk, which is the GNU version of a venerable old Unix command called AWK, named after three of the individuals highly involved in the early versions of AT&T Unix, takes input from a stream of data, formats in some way, and then prints out the modified stream of data to the screen. What a pipe does is change the default paths of input and output. Instead of printing to the screen, a pipe will redirect the stream of output that would normally have gone to the screen, so some other destination, like another program. As an example, consider the command:

```
$ echo "Now, sir, a war is never even, sir, a war is won" | gawk '{print $4,$6,$10}' | tr 'w' 'W'
```

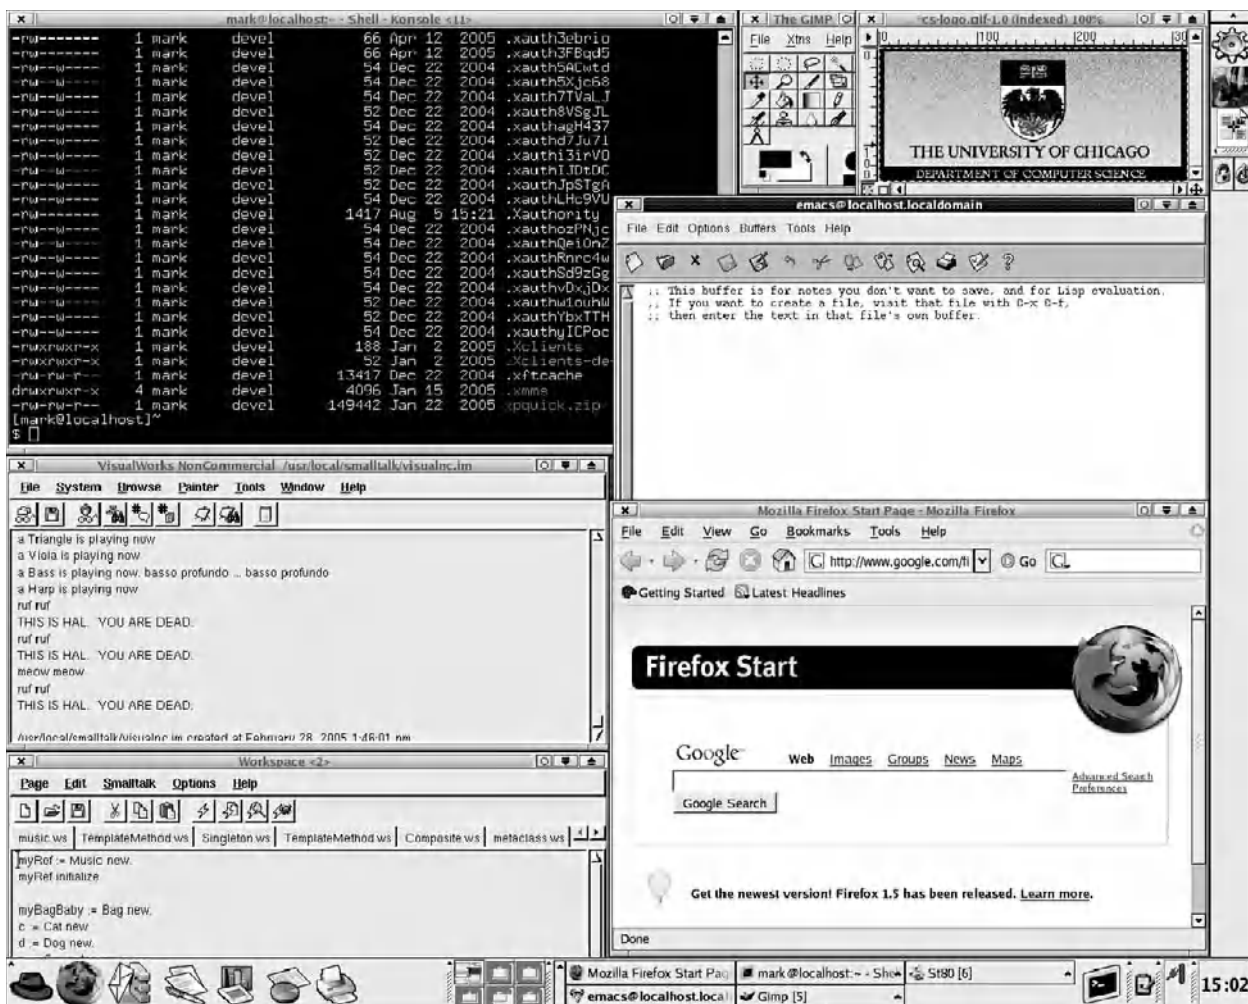

Figure 1: Typical Linux system screenshot

War never War

The “\$” is the standard shell prompt (for Bourne shell derivatives). We are echoing a famous palindrome, and the output of the echo command, which would simply be to reproduce the same text to the screen, is redirected by the pipe (the “|” symbol) to become the input to the gawk command. The result is that gawk takes in that string from echo, and prints out the fourth, sixth, and tenth words or “fields” of the string (only), ignoring punctuation. That yields the output stream “war never war,” drawn straight from the original. Then, this output from gawk is again piped (via the “|” symbol) to yet another utility, called “tr” (translate), and it replaces all instances of the “w” character with its capital form, “W.” The result of the pipeline of filters is “War never War.”

In Linux, as in other Unix systems, most everything is manipulated as a “file.” This means that as far as the programmer is concerned, a socket is just another file, the screen is just another a file, a tape device is just another file, a modem device is just another file, and all files are manipulated using just a few fundamental system calls such as open(), creat(), read(), write(), and close(). This Unix consistency is continued in Linux.

Fundamental common Unix priorities, such as portability, simplicity, consistency, and empowerment of the user are all exhibited in the Linux OS. Consistency and simplicity are already seen in the common Unix way of dealing with different devices—they are all seen and manipulated as “files.” Linux is written primarily in C, with only a small amount of native assembler, making Linux highly portable. This is the reason Linux has shown up on so many different hardware devices, because of its continuation of the Unix tradition of portability.

Finally, Linux, like other Unix operating systems, does not try to shield its users from the power of its operating system (or for that matter, try to shield its brittle operating system from its users). Instead, it lays it all out and opens up safe and controlled but open avenues so that the operating system can be manipulated, managed, and leveraged. Linux assumes its users are competent, resourceful human beings who can be trusted. This is not to say that controls and security are not in place to prohibit voluntary and involuntary malfeasance, but rather, the Linux philosophy is one of trust, access, and openness. Even the bugs known in Linux are advertised in the Linux man pages (another Unix tradition) (Gancarz, 1995).

Kernel Architecture

The kernel is the piece of the operating system that is loaded first—it’s the fundamental part of the operating system, the part that manages all the other parts. The kernel does two things primarily. First, it provides a communication gateway to the hardware of the computer, controlling software access to hardware and acting to some degree as a “traffic cop.” Second, the kernel provides an execution environment that can run multiple users’ programs while at the same time keeping these programs safe and functioning in a cooperative overall system.

The Linux kernel is a monolithic kernel as opposed to a microkernel such as exists in Minix or GNU Mach. This means that many features are resident within the kernel, including a single kernel memory space including all data structures. All kernel features, including device drivers, filesystems and networking code, all run within the single address space of the kernel. When the kernel is running, it runs in kernel mode only, never in user mode. This means that no user-mode code is ever running within the kernel. System calls go through a call-gate that shifts the processor into execution in kernel mode for the length of the system call. Once the system call returns, the user code begins again running in user mode.

Linux’s process model is Unix-based, providing a fundamental fork and exec model. Linux contains all the standard features one would expect in a Unix-like operating system, including virtual memory management, virtual filesystem support, lightweight processes, signals, System V interprocess communication, as well as symmetric multiprocessing. Linux (version 2.6) offers a fully pre-emptive kernel, meaning that the kernel can manage and manipulate multiple lightweight processes (LWPs) by managing the “time slices” or quanta that are given to each LWP as well as interrupting ones currently running but blocked (say waiting on some I/O) and put others onto the processor for temporary execution.

Linux can run on computers that have more than one physical processing unit or CPU. It can easily manage multiple users’ processes onto any number of multiple CPUs, a capability known as symmetric multiprocessing (SMP).

The Linux kernel is said to be “reentrant,” meaning that several programs can be in “kernel mode” at the same time on multiple physical processors, and in that sense, we can say that the kernel has been “entered more than once—by multiple processes at once.” A kernel can be reentered even on a single processor; if one process is blocked in kernel mode waiting on I/O and another process enters kernel mode while the first process is waiting. A reentrant kernel has to be more robust than a non-reentrant kernel, because as more kernel threads are active within the kernel, there is greater complexity and greater potential for conflict. On the other hand, having a solid reentrant kernel such as Linux provides the means for a significant performance boost for the overall operation of the system.

Processes and Threads

A process is a “cradle” of sorts in which a user program executes—it is the execution environment for a user program. A process is a place to store the current state of an executing program, including the stack, the heap, signal mask. But a process is not what “executes.” Rather, the process is the environment in which a program is executed, and it is a thread that actually does the “execution” of the program code. Thus, Linux allows for processes to have multiple threads that each may be scheduled onto a given physical processor, so that a single program can have multiple threads that are executing on its behalf simultaneously.

The OS ensures that user programs running in different processes are protected from each other. It would

be a shame if one user is running a chess program and another is running a word processing program and the latter attempts to type some text while the first user moves her queen and she sees the phrase “Be4xd5 Bishop takes Queen” appear on the term paper she is writing. Linux manages processes so that they are protected from one another; that there is no possibility that one process’s memory could become corrupted by the activity of some other process. The same management applies to the data written out to disk, information passed over a modem or socket.

Memory Allocation

Linux’s memory handling is a complex topic, but the central concept is that as in all Unix-like systems, Linux manages memory abstractly using something known as virtual memory. Basically, virtual memory is a logical construct that allows the physical memory to be (a) hidden and (b) appear much larger than it actually is. The net result of this abstraction is that multiple processes can be talking to the virtual memory abstraction simultaneously; processes can still execute even when not all of their memory is physically available; programs can be relocated in physical memory without the process needing to worry about that fact; and finally, programs can “think” they have much more memory than they actually have, which is managed by the virtual memory manager. In fact, a program can be loaded into a process with very little of its actual memory being physically allocated at load time. Only when specific memory is requested which is not there (known as a page fault), is that data actually physically loaded and then logically mapped, a process known as on demand paging. This allows many more programs to exist in memory than would otherwise physically be possible. Linux has a robust memory abstraction layer and is quite efficient at handling multiple programs manipulating virtual memory. The Linux memory handling layer allows for speedy caching of disk data as well.

I/O and the Virtual Filesystem

Linux uses object-oriented abstraction principles to handle multiple filesystems. Let’s address this using an example: one approach Linux could have taken was to hard code in the kernel the exact method by which a write would be conducted on say, an NTFS filesystem. We could call that `ntfs-write`. Then, in order to implement a method by which a write could be conducted on a DOS FAT filesystem, another version of write would be implemented in the kernel, say `dos-write`. The problem here is that in order to support the vast number of different filesystems, Linux would have dozens of multiple write-like functions to have to implement and manage. And then there is the problem that in Linux “everything is a file”—thus, you’d have to have a `modem-write` and a `socket-write` and a `terminal-write` and on and on and on.

Instead, Linux uses a virtual filesystem approach. What does that mean? It means it has a single write. One. It’s called `write()`. But, the single write “interface” has many different forms of implementation, many different methods by which write may be accomplished—all depending on the type of device being written to. Thus, each device implements its own version of write. The operating system just associates a driver with a particular device, and just

calls `write()` on it. The implementation of `write()` in each driver actually manages the writing, regardless of whether the target device is a network, a tape drive, a terminal screen, a modem device, a physical file on a Macintosh HFS filesystem or a UFS file on a NEXTSTEP filesystem, a Unix pipe, an ISO9660 CD-ROM drive, or whatever.

By virtualizing filesystem access, the programming interface (the API) can remain simple, and drivers supporting the myriad methods by which that API can be implemented can be written and loaded on demand (see Loadable Modules).

Scheduling

Part of the responsibility of the kernel is to make sure that all processes play fairly. This means that in a pre-emptive multitasking operating system like Linux, a system scheduler exists that measures the time each process (a program runs in what is known as a “process”) is allowed to run on a given physical processor. When one process’s time allotment is up (this is called a “quantum,” and is usually on the order of about a quarter of a second), the scheduler will have the kernel save the runtime state of that process and then move some other process onto the processor so it gets a chance to run (for its quantum). Now, certain processes have a higher priority than others, and for these special processes, they get a little advantage in their processor allocation. But by acting as a kind of fair-minded traffic cop, the scheduler still ensures that all processes get a chance to run in an equitable environment.

Loadable Modules

The Linux kernel can load “additions” to itself dynamically at runtime, through its loadable module capability. This means that support for additional devices (new CD/DVD drives, tape drives), filesystems (NTFS, HPFS), and networks (such as AppleTalk, ISDN) can be dynamically added to the Linux kernel at runtime. These additional modules still become part of the runtime kernel, but they do not have to be statically compiled into the kernel. This has several advantages. One, it keeps the default size of the kernel down, as well as giving users the ability to load additions to the kernel on an as-needed basis. If you do not have your DVD drive plugged in, you do not have to have the driver loaded into the kernel and taking up memory space. Linux’s loadable module capability comes with support for the management of modules, the registration of drivers, and a conflict resolution strategy for different drivers wanting to manage the same hardware device. Loadable modules are available for all sorts of different devices, including device drivers for printers, monitors, mice, disk drives, and network interfaces, as well as support for multiple filesystems and networking protocols. Loadable modules are highly useful in Linux, and enable the Linux monolithic kernel to be able to be squeezed onto a single 1.44 MB floppy disk, and still boot and run a computer.

System Architecture

Filesystem

The Linux filesystem is a hierarchical composite of directories and files, starting with a base directory called `root`.

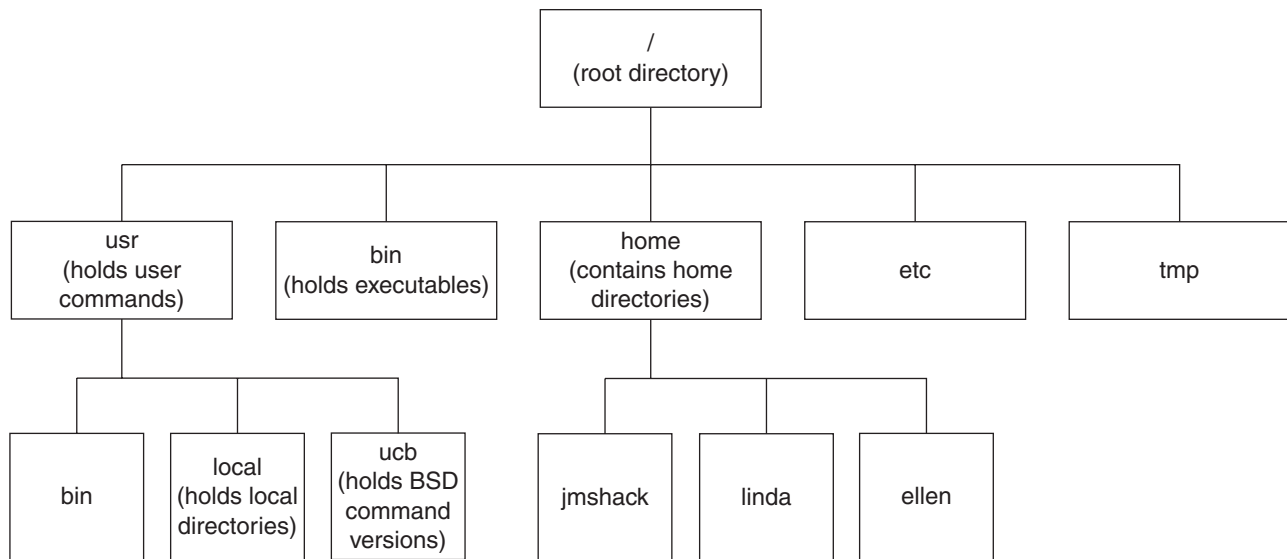

Figure 2: Typical Unix filesystem layout

Every directory in the filesystem, with the exception of the root directory, has a parent directory. All files on the system belong to a particular directory. Figure 2 shows a typical layout of a hierarchical Unix filesystem.

Table 1 gives the main directories and their functions on a typical Linux system.

The /home directory is significant because most users on a Linux system are assigned a default home directory, and this directory is stored under the /home directory. Therefore, a user with the username joe would usually have a home directory under /home/joe. A user's home directory is the current working directory immediately after the

user logs in, and it is the place where each user can store personal files.

Each file in the system is associated with a structure known as an inode. An inode (known as an information node) contains information relative to that particular file in the filesystem. The inode contains information about each file in the filesystem including the file name, the current size on disk in bytes, the type of file (regular file, directory, link, device), the number of hard links to the file, information indicating the user and group associated with the file, an identifier for the filesystem the file belongs to, and some timestamps representing when the file's contents were last read, modified, and when the inode structure itself was last modified. Most significantly, the inode contains pointers to the physical location of the file's data on the actual hard disk (Vahalia, 1996).

Table 1: Standard Filesystem Directories

/ (root)	The base directory of all other directories
/boot	The directory that holds the kernel and startup configuration for booting the Linux operating system
/bin	The directory that holds system binaries
/lib	The top-level library directory, which holds the static and shared libraries required to run the operating system.
/usr	The directory that contains user commands
/mnt	The directory that forms the default base mount point for mounting external filesystems, such as NFS directories, CDROM devices, etc.
/etc	The directory that contains system configuration files, including the files involved in system initialization
/tmp	A world-writable directory for storing temporary files (deleted periodically)
/home	The base directory for all users' home directories

Networking

Linux comes with vast protocol support for many different networking options, including base TCP/IP (including IPv6), Microsoft Windows SMB, Novell IPX/SPX, Apple Talk, WAN Networking including X.25, Frame-relay support, ISDN, PPP, SLIP, and PLIP, amateur radio, and ATM. It also comes along with support for more hardware than any other Unix-based operating system in existence.

Linux also supports enterprise computing including high availability solutions, RAID support, and redundancy, and, of course, standard Unix networking support if available, including support for Berkeley sockets, SUN NFS, NIS, NIS+, MMAP, SNMP, and so on. Linux can interoperate with a variety of network layers, in addition to Ethernet, including Fast Ethernet, FDDI, HIPPI, ireless LAN (802.11b and 802.11g), and Bluetooth (IEEE 802.15). An example of the overall architecture is seen in Figure 3.

This array of choices presents the Linux user with at once a great gift of variety, but it also comes with a liability in that most versions of Linux require some knowledge and industry on the part of the user in terms of

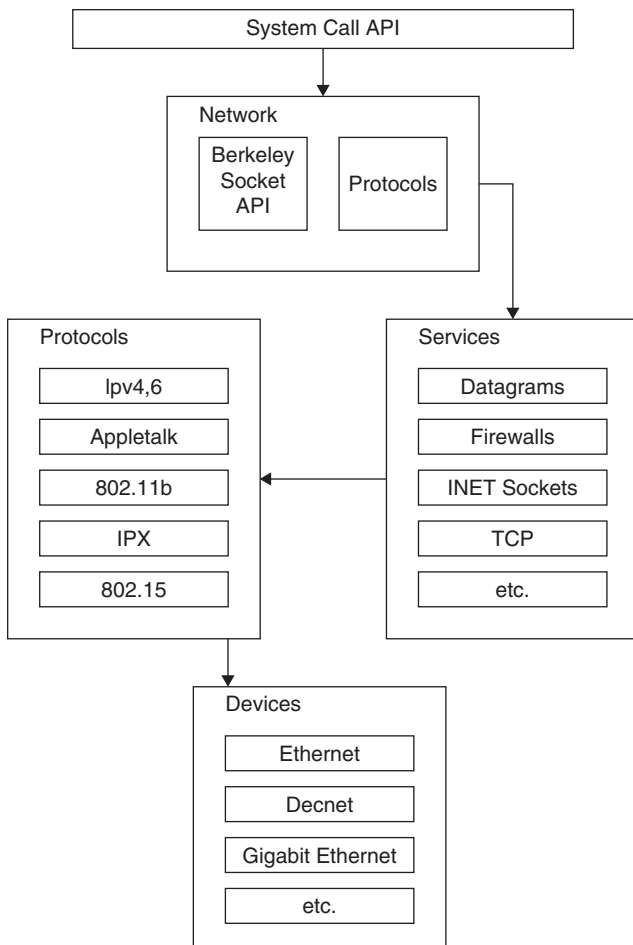

Figure 3: Network architecture

setting up and installing support for certain extensions. For example, although Linux supports wireless LAN, knowing what package to install, and then what configuration files to modify, and how to modify those files, is a bit daunting to the Linux newcomer. Linux does have a documentation project that attempts to keep up with a set of instructions for managing Linux, nevertheless, saying that Linux supports wireless LAN is one thing and successfully enhancing the kernel to support it and running it successfully is another. In addition, because Linux has to run on such a wide variety of hardware platforms (which, say Mac OS X does not), problems specific to a particular laptop or desktop system can always arise, and the answers can often take a while to resolve.

In addition, Linux extends its compatibility with other operating systems in that it can directly mount filesystems for a number of other operating systems, including MSDOS, Microsoft Windows, OS/2, Mac OS X, Solaris, SunOS, various BSD variants including FreeBSD.

Linux supports NFS and NIS/NIS+, with the standard configurations, so that Linux can mount NFS filesystems from other Unix systems, as well as offer its own filesystems as mountable, in addition to providing for centralized user management. Linux, through Samba, offers SMB compatibility so that users of Microsoft Windows can mount Linux file systems, allowing Linux to act

as an SMB file server, and participate in Windows domains and workgroups as a file server. Samba also offers SMB client capabilities, which offers command line utilities for browsing Windows directories from Linux. Linux can also act as a print server through various protocols, allowing it to publish printers to a given network.

Security

Linux security is based on standard Unix security metaphors, including user accounts, login security with secure passwords, filesystem protection, and file permissions. But Linux also supports data encryption and secure networking strategies (for example OpenSSH and secure shell), the use of smart cards and firewalls, packet filtering and TCP Wrappers, and Kerberos, just to name a few areas of security support in Linux.

One of the key advantages of Linux over certain other operating systems, such as Microsoft Windows systems, is its security. Instead of trying to be all things to all people who might wish to buy your product, instead, Linux tries and succeeds in offering a secure platform on which to run any number of different types of applications. One of the key enablers in terms of security include the new Security-Enhanced Linux (SELinux) offerings. SELinux is a version of Linux produced by the efforts of the Information Assurance Research Group, part of the National Security Agency (NSA) of the federal government, and the Secure Computing Corporation (SCC). SELinux provides, among other things, access control policies that confine user programs (including those run as the superuser) and system servers to the minimum amount of privilege they require to do their specific work. The result is a Linux system that protects information from access by other programs that should not be accessing that information.

User Interface

The default user interface in Linux is a shell known as bash, which stands for the Bourne Again Shell, a pun on the name of Stephen Bourne, who wrote the first user shell known as the Bourne Shell. The bash shell provides a command line environment for users to interact with the operating system, including running programs and managing user files. As part of the choices available in Linux, users are not stuck with the bash shell but can use any number of other shells, including the korn shell (ksh), the Z shell (zsh), the C shell (csh), and tcsh (DuBois, 1995; Rosenblatt, 1993). The different shells have different capabilities, but most modern shells offer a number of capabilities, including an interface for redirection, a facility for remembering and reproducing and editing recent commands. Users can even use commands from their favorite text editor (such as vi or emacs) in the editing of command lines previously executed. Also supported is command line completion, which allows the user to type some part of a file specification, and then hit a key, such as the tab key, which will prompt the shell to look for files that match the beginning specification. If the shell finds such a match, it will automatically complete the name.

Users can also specify alias names for commands, which can make certain commands easier to execute, or provide default options for certain commands. For

example, if you find yourself often typing a command such as:

```
/usr/bin/emacs -fn 6x13 -fg black -bg cyan -cr blue -ms
white filename.txt
```

which will set the default font and colors for an emacs session, you can transform this into an alias in bash by entering the following command:

```
alias myemacs="/usr/bin/emacs -fn 6x13 -fg black -bg
cyan -cr blue -ms white"
```

This allows the user to simply type "myemacs filename.txt" and emacs will then launch with the font and colors specified in the alias.

Shells also allow the user to create variables in memory and also provide a small programming language for writing shell scripts, which are commands contained in a file that the shell will execute on after another. Additionally, most shells on Linux support job control, which provides an interface into the multitasking capability of the operating system. A user can, from the shell prompt, issue a command and direct the shell to run the command "in the background." This is done by attaching an ampersand "&" to the end of the command line. Once done, the user does not have to wait for the command to finish, but is instead presented with another prompt to enter another command. Jobs in the shell can be managed, in that a user can recall to the forefront any command that has been sent to the background, as well as kill any of the jobs using the kill command.

ADVANTAGES OF LINUX

Linux is one of several open-source Unix-like operating systems (others include FreeBSD) that can be obtained and used for very little cost. In fact, if you want, you can go online to www.kernel.org and download the Linux kernel for free. If you want to obtain a more easily managed Linux installation, you can go to any number of online providers and get a full Linux system (including X Windows, package management), still for no cost other than your time (for a site full of options, visit <http://distrowatch.com/> for any number of different and flexible options for Linux). There are no necessary initial purchase fees with Linux, and there is no necessary annual maintenance or licensing fee associated either. If you want to obtain, install, and manage Linux at no cost other than your time, you are free to do so. However, you are "on your own" as they say in terms of the management and maintenance of your Linux installation. If you should wish to have support, you have several options. First, you can buy a packaged solution for Linux, say, from RedHat, and through paying a nominal charge (29 dollars to several hundred dollars), you get a short period of time (usually three months to a year) of online and or phone support to help you get along. Should you wish something more substantial in terms of support, there are several companies that provide different levels of maintenance support, everything from offering email support to on-site hand-holding. Obviously, the more on-site handholding

required, the higher your annual maintenance costs will be. But again, these costs are manageable and optional. Further, there are numerous online sites for support (in terms of usergroups) that are dedicated to various aspects of working with Linux, everything from administration issues, development issues, hardware issues, networking issues, security issues, as well as vendor-specific questions (like questions specific to RedHat for example). All of these groups can be found under comp.os.linux.*.

Linux has probably the best array of device support of any Unix system in the world. Part of the reason for this is derived from its open-source advantage. Because Linux is nonproprietary, as opposed to Apple's OS X or Sun's Solaris operating system, more hardware options exist for Linux and this is because Linux is not restricted to one or two specific hardware configurations (such as PowerBooks and iMacs and MacBook Pros). Having said this, it is often more difficult to connect a given device (say a digital camera for example) to a Linux system precisely because the supporting driver may be buggy or unavailable, as distinguished from a digital camera that can be plugged into a Mac Powerbook Pro and work "out of the box." Because Linux is "open" and untied to any specific vendor or hardware architecture, there are a myriad of devices that can be attached to a Linux system, but often not without some work and effort on your part.

Linux runs on a variety of different hardware platforms, including tiny devices with limited memory such as the Linux Wristwatch created at IBM Watson Laboratories (<http://www.eecs.utoledo.edu/~ewing/ieee/meetings/notices/25sep2002.pdf>). Of course it can run on the full array of Intel-based computers also. It can just as easily run on an old 80386 machine with as little as 4 megabytes of memory or be embedded on tiny hardware platforms such as cell phones and PDAs. Linux was the operating system of choice on the original TiVo® digital video recorder. In addition, Linux can also run on Sun Sparc hardware as well as on the IBM 390 mainframe (cf. the "Iron Penguin" at Princeton University and <http://linuxvm.org/index.html>). It can run on a PowerPC along side of the Mac OS. Today, Linux can be built to run on Alpha, Motorola 68000, PowerPC, 32-bit and 64-bit Sparc, Mips, and many other architectures. Although it can run on a wristwatch, Linux also supports the TeraGrid (coordinated through the Grid Infrastructure Group [GIG] at the University of Chicago) and Linux NetworX Evolocivity at Lawrence Livermore Laboratories. Evolocivity was designed to run on approximately 2000 multiprocessors running at 2.4 GHz with a theoretical peak of 9,200,000,000,000 (9.2 trillion) calculations per second (by contrast this is approximately 27 trillion times faster than the original IBM PC introduced in the early 1980s).

Linux is solid and powerful. It tends to function well and not crash as often as some other proprietary operating systems. The average uptime of the average Linux computer is significantly longer than say the average uptime of a Microsoft Windows XP computer. The reasons for this are many, but suffice it to say that Linux is simply a solid and durable system. Linux is also fast and efficient. Developers working on some aspect of Linux number in the tens of thousands, and the core programmers are extremely talented and the intellectual capital at your

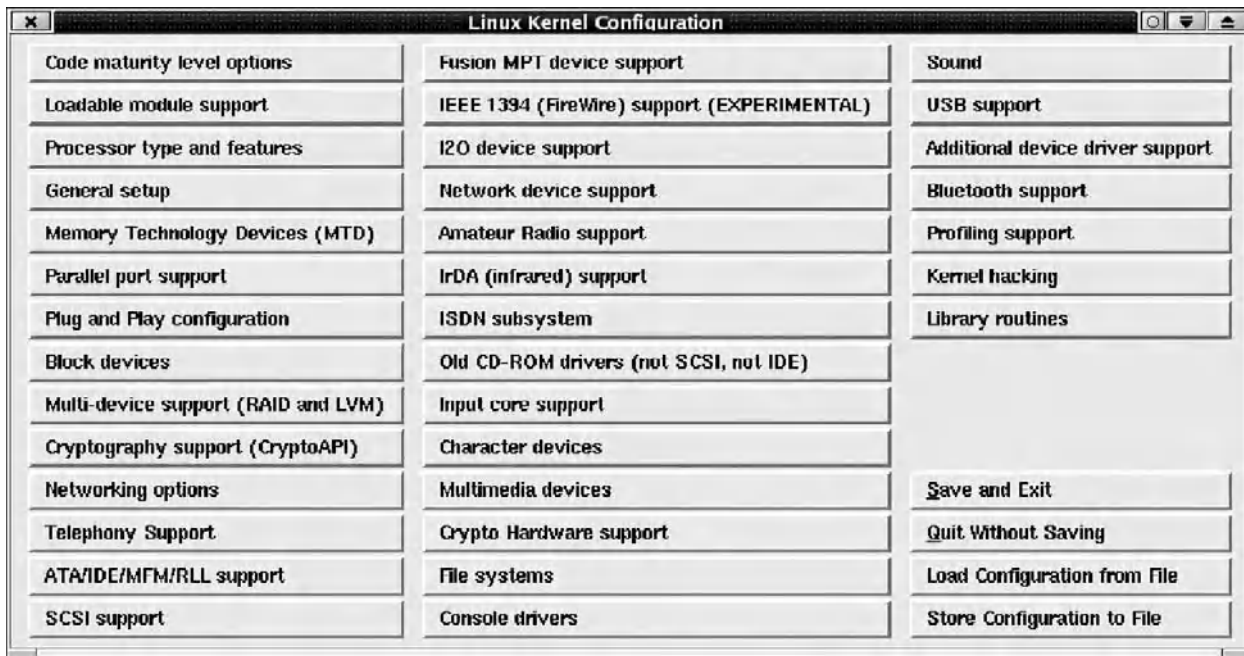

Figure 4: Screenshot of build configuration main screen

disposal on the Linux front simply is not available from any particular proprietary vendor, no matter what the resources of that vendor. Further, since the source code is open and freely available, when bugs exist, they tend not to exist for very long, because so many eyes are looking at the code. Linux is supposed to have once said that given enough eyes, all bugs are shallow. This means that if you have enough talented people working on a problem, a best-of-breed solution should be readily available.

Linux is also compatible with other systems. This is partly because it had to be—it started that way. The original Linux kernel was built on another system (Minix) and actually used its filesystem (minix). Since then, Linux was dual-booted on many Microsoft Windows systems, so, from the beginning, it had to be a good cooperative computational citizen. This means that Linux systems can directly mount and share files with a variety of other systems, including Microsoft Windows NT, OS/2, SVR4, Mac OS X, Solaris, SunOS, NEXTSTEP, FreeBSD, OpenBSD, and so on. Linux is also able to communicate over the network with these different filesystems over various protocols. For example, a Linux system can store and retrieve files on a Windows XP machine because of an add-on product called Samba that provides the Windows SMB protocol for Linux. Linux can also act as a file server for many other operating systems.

Linux, even more than most Unix operating systems, wants to give its users choices. As for user interfaces into the operating system, the text-based shells available by default as options for users to choose include the default bash shell, csh, tcsh, ksh, pdksh, zsh, and ash, just to name a few. As for graphical interfaces and window managers that run on top of X Windows, we can choose from Gnome, KDE, WindowMaker, Enlightenment, ICEwm, BlackBox, and Sawfish, just to name a few of the dozens available.

Figure 4 shows the main configuration screen for Linux and gives some hint as to the level of configuration that is available on Linux.

Note that the depth of options behind each one of these buttons is itself vast. For instance, just a drive into the “SCSI support” configuration would reveal further options including disk, tape, CDRom, and lower level drivers could be chosen from a list that includes standard SCSI drivers such as Adaptec, AMI MegaRAID, Buslogic, Compaq, Future Domain, Intel, IOMEGA, NCR, Qlogic, Seagate, UltraStor, just to name a few. Additionally, PCM-CIA-based SCSI can be selected from vendors including Adaptec, Future Domain, NinjaSCSI, and Qlogic.

CONCLUSION

Linux is a solid, dependable, multiuser, multitasking operating system based on the Unix philosophical tradition. It is open source, meaning that you may obtain it, compile it, and run it at no monetary cost. It is freely available to all, and is modifiable by the community of users (with some coordinating restrictions), which in turn enriches the overall system available to all. It has given wind to the sails of the open-source movement, and has provided a solid, dependable platform on which much scientific work has been conducted. It has shown, like Unix, that much can come from hard work and a little bit of brilliance in a single individual who has nothing much else to do for a few months.

There are, however, problems associated with managing so much choice and so many configurations. Precisely because there is a driver for just about every new technology and hardware device that comes onto the market, the availability of hardware support in Linux is substantial. But this ubiquitous support comes at a cost. It is difficult for established Linux vendors to offer easy

configuration tools for the variety of hardware and technology options available. Further, because of the way the kernel is structured, adding a new device often requires recompilation of the kernel itself. Although this is not terribly difficult, it can be daunting for the average or first time user. There are former Linux users who have switched to other operating systems, including Microsoft Windows and Mac OS X and free BSD derivatives, from Linux, precisely because of the complexities centered around managing and configuring a Linux system. It can be difficult to install a version of Linux onto a specific laptop, and expect that the laptop's modem, wireless LAN, Bluetooth, and even recovering from sleep when the laptop lid is closed and re-opened, will all work flawlessly the first time. This is in many cases unlikely. With a system such as Mac OS X running on, say, an Apple PowerBook, this is trivial stuff that requires little if any management or configuration. Not so with Linux. Some Linux distributions, for example, Gentoo Linux, have made the move to automated updating of the OS, so that the user can just "leave it running" and the OS would download updates as they become available. This is nothing new, Microsoft Windows does the same thing now, and Redhat at least for its distribution has been providing a similar service. Nevertheless, there is a substantial onus on Linux users to be "up to the task" of configuring and maintaining their free OS.

In the end, Linux is a highly capable free OS that provides its users with a variety of choices in terms of hardware and software. It can interoperate with other systems, both from a filesystem standpoint as well as from a networking standpoint. It is fast, reliable, and has support that allows it to act as a print server as well as a file server to other systems. Although it is far from perfect, it nevertheless has been instrumental in offering a cost-effective alternative to commercial software, and it has advanced the cause as well as the acceptance of free, open-source software, in the corporate world as well as in academia.

GLOSSARY

- API:** Application programmer interface. A library of functions that are callable as routines.
- Bit:** The smallest unit of information on a digital computer, standing for binary digit. A bit can have the value 1 or 0, meaning on or off.
- Boot:** The process of initializing the operating system on a computer by initializing hardware and establishing a sane environment in which users can work on the system.
- BSD:** Berkeley Software Distribution. One of the two major variants in Unix, begun during the mid-1970s by the Computer Systems Research Group at the University of California, Berkeley.
- Byte:** Eight bits of data on a digital computer. A byte generally contains a single character (like the character "a") or a small integer (generally less than 128 or 256).
- Command substitution:** The ability of a shell to execute a command and substitute the output of that command in another command.
- Filter:** A special type of program written to take its input from standard input files and write its output to standard output. Filters may be linked together using pipes. Grep and sort are two types of filters.
- Function:** A routine that is callable in a procedural programming language, such as C. A function promotes the concept of modularity in program design.
- Inode:** A fundamental data structure that holds information pertaining to a particular logical file on the filesystem. An inode holds information about the file such as its size in bytes, modification dates, security and access information, type of file, and the location of the data on the physical device.
- Job control:** An ability of the shell to run multiple programs at the same time, and a facility to manage multiple programs running in the background and foreground.
- Kernel:** The main "brain" of an operating system, providing an interface between the hardware itself and providing resource allocation services to the rest of the user system.
- MMAP:** Sun's memory mapped access protocol
- Multitasking:** The ability of an operating system to run more than one process at the same time, either on multiple physical processors or by quickly swapping tasks on and off of a single processor, giving the illusion of running multiple processes simultaneously.
- Multiuser:** The ability of an operating system to support more than one user at a given time.
- NFS:** Sun Microsystem's network filesystem. A set of services that allows users to access files on separate filesystems.
- NIS:** Sun Microsystem's network information services. A set of services to centrally manage users on a network.
- Operating system:** The fundamental control program on a computer, which provides a functional environment in which users can interact with the computer.
- Pipe:** A special connector that passes through a stream of text from one end to another. Special programs known as filters can connect their various inputs and outputs to a pipe, and therefore communicate over the pipe.
- Process:** A structure that provides an execution context for a given program, providing memory resources, terminal IO support, process state, file descriptors.
- Program:** A compiled and linked executable file that runs natively on the operating system, in order to execute some capability on behalf of the user.
- Prompt:** An indicator from a shell (usually in the form of "\$" or "%") that it is ready and waiting for input.
- Quantum:** A period of time, usually in milliseconds, during which the scheduler runs a program on a processor.
- Regular expression:** A string composed of literal characters and special symbols that can represent a potentially larger domain of possible resolutions.
- Shell:** The primary user interface in a Unix system, allowing the user to interact with the computer by issuing consecutive commands.
- Signal:** A brief message that one process may use to contact another process.

Socket: A BSD-defined standard interface that allows two computers to communicate over a network. The standard interface for connecting to the Internet.

System call: A function in the kernel's API that offers user programs the ability to request services from a running kernel.

INTRODUCTION

Metropolitan area networks (MANs) were developed to meet the need for a very high-speed networking capability that would fill the technology void that existed between the availability of high speed local area networks (LANs) in the enterprise and wide area networks (WANs). WANs consist of common carrier circuits and switches. Originally these circuits were low-speed voice-grade communications channels that were used to transmit data from a terminal to a remote computer. Later, these voice-grade circuits were replaced first by digital and then by optical circuits that enabled high-speed communications to take place between remote computers.

LANs were developed to provide high-speed communications within a user's facility. They enabled an organization to link together all its computers at a site to support such applications as file sharing and printing. In addition, LANs enabled an organization to be able to access external networks through a single interface. By attaching a router to the LAN, an organization could communicate over the Internet or use a WAN to transfer data to its offices in different cities, states, or countries. What was missing from this scenario was the ability for an organization to communicate efficiently between its offices in a city. MANs were developed to fill this need for a high-speed network within a metropolitan area.

Just as the IEEE 802.3 and 802.5 Working Groups had taken the lead in the development of standards for Ethernet and token ring LANs in the early 1980s, the IEEE 802.6 Working Group developed the first MAN standard in 1987 (Institute of Electrical and Electronics Engineers, 1990). The IEEE 802.6 standard specified the media access control (MAC) and the physical layer (PHY) for a distributed queue dual bus (DQDB) MAN. In order to be able to support very high-speed communications, the 802.6 PHY

specified the use of optical fiber for the communications medium. The DQDB MAN was the basis for the switched multimegabit data service (SMDS) that was developed by the telephone companies (telcos) (BellSouth Telecommunications, 1994). SMDS provided a high-speed communications service for LAN connectivity within a metropolitan area.

An enormous amount of optical fiber cable was laid by the telcos to provide the high-speed communications circuits needed to implement MANs. With the development in 1988 of the Synchronous Optical Network (SONET) standard by the American National Standards Institute (ANSI) in the United States (American National Standards Institute, 1995) and the similar Synchronous Digital Hierarchy (SDH) standard in Europe by the International Telecommunications Union Telecommunications Standardization Sector (ITU-T) (International Telecommunications Union, 2000), there now existed a common specification for multiplexing lower speed T1/E1 telephone network circuits onto a high-speed optical fiber circuit. Dual-ring SONET/SDH-based MANs were used to carry LAN and other broadband data traffic within a metropolitan area. The data were either carried directly in the SONET/SDH payload or the asynchronous transfer mode (ATM) protocol was used to carry the data over the SONET/SDH network. To provide the ever-increasing need for more bandwidth, dense wave division multiplexing (DWDM) was developed during the mid-1990s that enabled the data-carrying capacity of optical fiber cables to be increased by a factor of 80 or more (Fujitsu Network Communications, Inc., 2002).

Starting in the late 1990s, the IEEE 802 committee began the development of two new wireless standards for MANs. IEEE 802.16 is a high-speed wireless standard (dubbed WirelessMAN) that uses both the licensed and

the license-exempt portions of the gigahertz (GHz) radio frequency (RF) spectrum. The 802.16 standard supports point-to-point, point-to-multipoint and mesh configurations. The initial IEEE 802.16 standard was approved in 2001. It covers the frequency spectrum from 10–66 GHz and provides line-of-sight (LOS) communications between a user site and a network hub. An addendum to the standard, approved in 2003, provides for non-line-of-sight (NLOS) communications in the 2–11 GHz portion of the RF spectrum (Institute of Electrical and Electronics Engineers, 2004a). The IEEE 802.16e standard, approved in 2005, adds a mobile capability to the Wireless MAN standards for subscribers moving at vehicular speeds (Institute of Electrical and Electronics Engineers, 2005). The IEEE 802.20 working group is also developing a wireless standard for mobile users at vehicular speeds up to 250 km/hr for the transport of IP data (Klerer, 2003).

Wireless MAN standards similar to IEEE 802.16, called HIPERACCESS and HIPERMAN, are being developed within the Broadband Radio Access Networks (BRAN) project of the European Telecommunications Standards Institute (ETSI). The HIPERACCESS standard was originally published in 2002 (European Telecommunications Standards Institute, 2002). It addresses the higher portion of the frequency spectrum above 11 GHz. The HIPERMAN standard, published in 2005, is being developed to provide an interoperable broadband fixed wireless access network in the 2–11 GHz RF spectrum (European Telecommunications Standards Institute, 2005). Both HIPERMAN and HIPERACCESS are being harmonized with the IEEE 802.16 standards to provide a worldwide standard for wireless MANs.

Another new standard being developed by IEEE is the 802.17 Resilient Packet Ring (RPR) MAN that was approved in 2004 (Institute of Electrical and Electronics Engineers, 2004b). RPR employs optical fiber circuits in a dual counter-rotating ring configuration that is optimized for packet transmission. However, unlike other dual ring MANs, the IEEE 802.17 RPR uses both rings for communications. It provides for efficient communications through the use of concurrent transmission, bandwidth reclamation, bandwidth reallocation, spatial and temporal bandwidth reuse, and traffic prioritization.

In addition to the standardization work being done by the IEEE 802 Working Groups, a number of industry forums have been formed to promote the development and implementation of these standards. The Worldwide Interoperability for Microwave Access (WiMAX) forum was formed in June of 2001 for the purpose of promoting the development of the 802.16 WirelessMAN standards (WiMAX Forum, 2006). The Metro Ethernet Forum was formed in September of 2003 to promote the use of high-speed Ethernet MANs (Metro Ethernet Forum, 2006). The Metro Ethernet forum has developed a number of specifications for implementing Gigabit and 10 Gigabit Ethernet MANs using either a point-to-point or a multipoint-to-multipoint configuration.

MAN FUNDAMENTALS

The principal technology alternatives that determine the nature of a MAN are its transmission media, topology, and the communications technology that it uses to transmit

data. The transmission media is the physical path between the transmitter and receiver in a communications network. The topology of a network refers to the physical configuration of the communications media that interconnects the communicating devices. The communications technologies are the protocols that are used to transmit the user data over the network.

LANs vs. MANs vs. WANs

A local area network (LAN) is a communications network that provides a direct interconnection for a variety of computing devices. The distinguishing features of a LAN are its size and its speed. A LAN covers a small geographical area; in most cases it is limited to a diameter of 200 meters. The data rate of the LAN can be anywhere from 10 Megabits per second (Mbps) to 10 Gigabits per second (Gbps). Other characteristics of a LAN are its low bit error rate (from 10^{-9} to 10^{-12}) and its inexpensive interfaces. Finally, unlike WANs and MANs, the LAN is owned by a single private organization. Thus no recurring communications costs are incurred when using the LAN.

A metropolitan area network (MAN) is a high-speed communications network that provides a means for interconnecting LANs over an area as large as a small city. A MAN covers a much larger geographical area than a LAN; it has a maximum diameter of 100 to 150 kilometers. The data rate of a MAN can range from 155 Mbps (STM-1) to 10 Gbps (STM-64). Because the communications circuits that comprise the MAN are optical fiber, it has a very low bit error rate (from 10^{-11} to 10^{-12}). However, the cost to interface devices to a MAN is higher than that of a LAN. Finally, because of its large geographical coverage, MANs are owned by telcos as opposed to a private organization. Thus the cost to use a MAN will be higher than that of a LAN because usage charges must be paid to the network provider.

A wide area network (WAN) provides the means for interconnecting LANs and MANs over a very large area. The geographical extent of the WAN is essentially unlimited; it can be national or international in size. A WAN consists of a group of routers and/or switches that are connected together by public switched telephone network (PSTN) circuits. Depending on the type of circuits used, a WAN can support data rates from 64 Kbps (DS0 circuits) to 10 Gbps (SONET OC-192/STM-64 optical circuits) or more. As is the case with MANs, WAN circuits are provided by the telcos. The WAN bit error rate ranges from 10^{-6} to 10^{-12} depending on the type of circuits used and the technology employed to construct the WAN. The cost to use the WAN will depend on the extent of the WAN and the technology used. However, the cost will be higher than a LAN because usage charges must be paid to the network provider. Figure 1 shows examples of LAN, MAN, and WAN topologies.

MAN Media

As a result of the requirement for very high data rates, the media used to construct a MAN are limited to those with very large bandwidths. Therefore, optical fiber cable and the Gigahertz (GHz) portion of the radio frequency (RF) spectrum are the only two alternatives that are used. An optical fiber cable consists of a thin glass core that is

Figure 1: LAN, MAN, and WAN topologies

surrounded by another glass material (called cladding) with a lower index of refraction where the index of refraction, n , is a measure of the speed of light in free space, c , divided by the speed of light in the glass material. Because c is the maximum obtainable speed, the index of refraction is a number greater than 1.

The phenomenon of total internal reflection is used to transmit the light signal through the optical fiber medium. As shown in Figure 2 (ray 1), light going from a dense (higher index of refraction) medium to a less dense (lower index of refraction) medium will bend away from the normal (a line perpendicular to the medium). As the angle of incidence increases, the angle of refraction approaches 90 degrees (ray 2). The critical angle occurs when the angle of refraction equals 90 degrees (ray 3). Light transmitted at an angle greater than the critical angle experiences total internal reflection (ray 4). The light

Figure 2: Total internal reflection

pulses are confined to the medium and the angle of incidence equals the angle of reflection. These light pulses can travel very large distances with very little attenuation. Because light consists of electromagnetic waves in the frequency range of 10^{14} – 10^{15} Hz, an optical fiber cable has a very large bandwidth. Thus an optical fiber cable is capable of supporting extremely high data rates (10 Gbps to 40 Gbps and higher).

Unguided media (i.e., free space) can transport electromagnetic waves without the use of a physical conductor. The electromagnetic spectrum that is used for communications extends from very low frequencies (3 KHz) to extremely high frequencies (30 GHz to 300 GHz). The lower end of the frequency spectrum is called radio waves. The upper end of the frequency spectrum is called microwaves. By modulating the frequency, amplitude, and/or phase of an electromagnetic wave (Figure 3), it can be used to carry information through free space. Because the bandwidth used in the microwave portion of the frequency spectrum can be made very large, data can be transmitted at very high data rates (100 Mbps and higher).

MAN Topologies

The topology of a network refers to the physical configuration of the communications media that interconnects the communicating devices. There are four main topologies that are used in MANs: ring, point-to-point, point-to-multipoint, and mesh. A ring network consists of a closed loop of nodes (Figure 4d). Each node is connected to the

Figure 3: Amplitude, frequency, and phase modulation

previous node and the next node by a point-to-point link. Data circulates around the ring from node to node in either a clockwise or a counterclockwise direction. With a dual-ring configuration data travels clockwise on one path and counterclockwise on the other path. Because data circulates past each of the nodes on the ring, a packet sent by one station attached to the ring can be seen by all stations attached to the ring. Thus a ring acts as a shared media broadcast network. Dual-ring configurations are used for reliability. If one of the rings fails, the other ring can be used for backup.

A point-to-point (P-P) topology consists of a communications circuit that connects two fixed nodes (see Figure 4a). The P-P topology provides a user at a site with

a fixed bandwidth with which to communicate with a network hub. This enables the user to have a guaranteed bit rate for communications. In a wireless network, the P-P link provides line of site communications between the user and the network hub.

A point-to-multipoint (P-MP) topology consists of a star configuration in which a number of users communicate with a central hub (see Figure 4b). The users must send data through the hub to communicate with each other or with other users attached to external networks. The hub acts as a repeater to pass traffic from one user to another user. A switch or a router is used to communicate with users on external networks.

A P-MP configuration can be directly implemented in a fixed wireless network. The network base station transmits data in the downstream direction to a number of subscriber locations. A modulation technique is used to assign a portion of the frequency bandwidth to each of the subscriber locations so that only the appropriate subscriber station will receive the data being sent to it. In the upstream direction, the P-MP network multiplexes the individual user transmissions into a high data rate channel for transmission over the external network.

A mesh network consists of a number of nodes that are connected to each other through P-P links. Each node can communicate with two or more nodes, so that unlike the ring configuration there are multiple paths between each of the nodes (see Figure 4c). With a mesh network each node acts as a repeater as well as a user interface. In a wireless environment a mesh network enables any node to communicate with any other node in the mesh network through one or more hops. The mesh topology solves the problem of communicating between nodes when there is no direct line of site (LOS) communication path between the nodes.

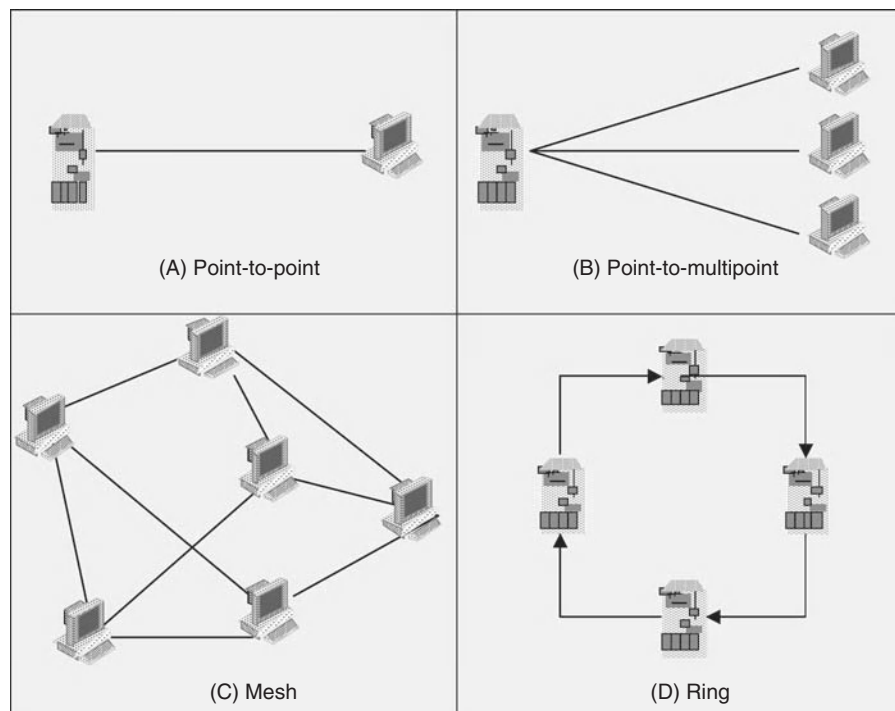

Figure 4: MAN topologies

MAN Communications Technologies

A number of communications technologies have been used to implement MANs including SONET/SDH, ATM, DWDM, and Ethernet. SONET/SDH was the initial technology used. It was originally developed as an optical transport technology to provide higher capacity circuits than the existing T1/E1 digital circuits. SONET/SDH provides a multiplexing scheme for combining data streams at multiples of the synchronous transport signal (STS) level 1 data rate of 51.84 Mbps. In a similar manner SDH multiplexes data streams at multiples of the synchronous transport module (STM) level 1 data rate of 155.52 Mbps. The SDH multiplexing scheme is exactly three times the rate of the SONET multiplexing scheme. Both the SONET and the SDH standards specify the method for multiplexing T1/E1 data streams within the basic STS-1/STM-1 frame (Goralski, 2002).

Because SONET/SDH was originally designed to carry circuit switched traffic, it was not optimized for transporting packet data. Thus the ITU-T specified that ATM was to be used to carry packet data. ATM provides a mechanism for partitioning packet data into 53 byte cells that consist of a 5-byte header and a 48-byte payload. An ATM adaptation layer (AAL) specifies how the packet data is to be encapsulation and segmented to fit into the ATM cells.

DWDM is used for transmitting multiple data streams over a single optical fiber. DWDM makes use of the fact that a light pulse is made up of a large number of wavelengths. Each wavelength can be used to transmit a separate data stream over a single optical fiber. Thus, by using DWDM it is possible to simultaneously carry 80 or more SONET/SDH data streams over an optical fiber.

Ethernet has become the dominant technology for LANs in the enterprise environment. Originally Ethernet had a data rate of 10 Mbps. As more and more traffic was

being sent over LANs, higher speed versions of Ethernet were specified. With the development of Gigabit and 10-Gigabit Ethernet, the data rate was now fast enough for Ethernet to be used as a MAN technology. Because these high-speed versions of Ethernet were designed to run over optical fiber cables it was possible to transmit Ethernet over the much longer distances needed for MANs than the 200-meter limit of twisted-wire pair. Also, the 10-Gigabit Ethernet standard specified the use of SONET STS-192/SDH STM-64 circuits to transport the Ethernet frames.

DATA TRANSPORT OVER MANs

An encapsulation technique is used to enable SONET/SDH to carry packet data. The packet data is carried within the SONET/SDH synchronous payload envelope (SPE). With normal SONET multiplexing, a SONET STS-N frame is composed of N STS-1 frames. Thus an STS-3 frame contains three separate STS-1 frames that are time division multiplexed together a byte at a time. For the encapsulation technique to work efficiently, it is therefore necessary to replace the individual SONET/SDH payloads with a concatenated payload.

Continuous Concatenation

In order to have a signal that supports the full data rate of an STS-N, SONET allows for the combining of the SPEs from lower speed SONET circuits into a single high-speed SPE. The mechanism for doing this is called contiguous concatenation (Kartalopoulos, 2004). With contiguous concatenation the payload of an STS-3 frame is treated as a contiguous group of bytes as opposed to three separate STS-1 SPEs (Figure 5). Instead of having 3 separate STS-1 51.84 Mbps data streams carried in an STS-3, the concatenated STS-3 is a single 155.52 Mbps data stream.

Figure 5: Multiplexed vs. contiguous concatenation frame

This concatenated frame is called STS-3c to distinguish it from a normal multiplexed STS-3 frame.

ITU-T specified the use of contiguous concatenation to transmit ATM cells over SONET/SDH. Data from an application is fragmented to fit into each ATM cell and reassembled at the destination. The SONET/SDH circuit transparently carries the ATM cells from the source to the destination node. ATM can provide different levels of QoS for each of the data streams it is transporting.

Virtual Concatenation

Contiguous concatenation was developed to provide an efficient procedure for transporting packet data over SONET/SDH. However, unless the data rate of the packet data matches the data rate of the SONET/SDH channel, it is necessary to send the packet data over a higher rate SONET/SDH channel. This led to an inefficient use of the SONET/SDH bandwidth. For example, sending 10-Mbps Ethernet over an STS-1c channel uses less than 20% of the STS-1c bandwidth. To enable packet data to be efficiently sent over a SONET/SDH channel, the technique of virtual concatenation (VC) was developed. VC enables SONET/SDH to match the bit rate of the packet data by using multiple slower speed SONET/SDH channels (Cavendish et al., 2002).

VC, in combination with the Generic Framing Procedure (see Generic Framing Procedures) allows the efficient mapping of packet data over SONET/SDH. VC allows a high data rate packet channel to be segmented and transmitted over multiple lower rate SONET/SDH channels. Each lower channel can be transported independently using different SONET/SDH payloads. At the destination node, the original packet data is reassembled from the independent SONET/SDH payloads.

The lower speed channels that comprise the high data rate stream are specified in SONET as STS-n-Xv, where n is the STS signaling level (1, 3, 12, etc.) and X is the number

of these channels that are being used. (SDH uses the terminology STM-1-Xv to identify the number of STM-1 payloads that are being used for virtual concatenation.) For example, using STS-3c-7v, a 1-Gbps Ethernet data stream is partitioned into seven STS-3c channels that have a total data rate of 1.09 Gbps (Cavendish et al., 2002).

In addition to VC, a new capability, called the link capacity adjustment scheme (LCAS), has been developed to allow the dynamic adjustment of the size of a virtual concatenated SONET/SDH channel to meet periodic changes in user bandwidth requirements. LCAS provides a control mechanism to dynamically increase or decrease the number of VC channels assigned to a user to meet changing bandwidth needs. LCAS uses the H4 byte in the SONET/SDH header to pass the control information needed to reconfigure the link (Cavendish et al., 2002).

Classical IP over ATM

A number of framing procedures have been specified for carrying IP packet data over SONET/SDH. A straightforward solution is to first encapsulate the IP datagram in ATM cells and then have the SONET/SDH frame carry the ATM cells. Request for Comment (RFC) 1577, Classical IP over ATM, specifies the method of encapsulating IP in ATM cells (Lauback, 1994).

The ATM Adaptation Layer Type 5 (AAL5) is used to adapt the IP datagram to the ATM format (Figure 6). An 8-byte header is prepended to the IP datagram. The header contains the logical link control (LLC) and the subnet-network access protocol (SNAP) frames that identify the content of the SNAP protocol as IP data. A pad and an 8-byte AAL5 trailer are appended to the IP datagram. The pad is used to make the complete AAL5 frame an exact multiple of the 48-byte ATM payload so that the AAL5 trailer can be located within the ATM cell payload. The trailer contains the length of the IP datagram and a CRC that is used to determine if the reassembled IP datagram contains

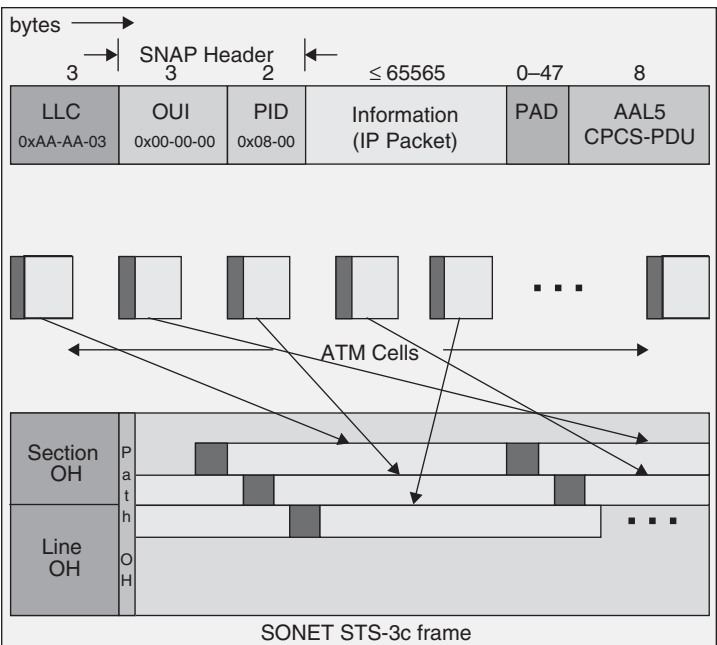

Figure 6: Classical IP over ATM

Figure 7: IP over SONET

any errors. The complete AAL5 frame is then fragmented into 48 byte segments that are placed in the payload of the ATM cells. Finally the ATM cells are mapped into the concatenated SONET/SDH payload for transfer over the network (Bonenfant and Rodriguez-Moral, 2001; Grossman and Heinanen, 1999).

IP/PPP over SONET/SDH

By using ATM to carry IP datagrams, it is possible to provide QoS for the transfer of the data; however, this procedure incurs a penalty of a significant increase in the size of the frame overhead (up to 25%). Packet over SONET/SDH (POS) is used to get around this problem. The ATM encapsulation is removed and the IP datagram is sent directly over the SONET/SDH circuit. RFC 2615 and ITU-T standard G.707 specify the use of the point-to-point protocol (PPP) over SONET/SDH to carry IP traffic (Figure 7) (Malis and Simpson, 1999; International Telecommunication Union, 2000).

The IP datagrams are first encapsulated inside PPP. The PPP header field is one or two octets long. A value of 0x0021 indicates that the PPP information field is carrying IP data. The high-level data link control (HDLC) protocol is used to frame the PPP encapsulated IP datagram. The flag field (0x7F) at the start of the HDLC frame enables PPP encapsulated IP datagrams to be delineated on the synchronous transport link. The cyclic redundancy check (CRC) in the HDLC frame FCS field provides error detection. The HDLC frame is then mapped byte synchronously into the SONET/SDH SPE.

To avoid frame misalignment, byte stuffing is used to prevent random bytes in the data from mimicking the HDLC flag field. When a flag field appears in the data, it is exclusive or'd with 0x20 and the escape sequence 0x7D is inserted in front of it. The same procedure is carried out when the escape sequence 0x7D appears in the data. Thus, 0x7E is encoded as 0x7D 0x5E and 0x7D is encoded as 0x7D 0x5D. However, byte stuffing has the undesired effect of increasing the overhead in the data stream (Scholten et al., 2002).

IP over DWDM

With the exponential growth of the Internet during the 1990s, the type of data being sent over MANs went from mostly circuit switched voice traffic to a preponderance of IP packet data. The telcos were thus faced with the problem of carrying huge amounts of IP packet data over their SONET/SDH networks. However with the development of WDM technology during this same time period there was a potential solution to this IP problem. The use of DWDM technology was able to increase the capacity of the telcos optical fiber cables by two orders of magnitude. A number of architectures were proposed to enable the existing SONET/SDH infrastructure to carry the IP packet data (Metz, 2000).

Initially, a four-layer IP over ATM over SONET/SDH over DWDM architecture was used. ATM equipment was employed to carry the IP traffic (Figure 8a). The ATM cells were sent inside the SONET/SDH frame. Then the SONET/SDH frame was mapped into one of the DWDM wavelengths. However this solution was inefficient for a number of reasons. First the 5-octet ATM cell header adds overhead to the transmitted data. In addition, the bursty IP traffic may not fully utilize the SONET payload. Finally, this approach requires four separate management layers.

The second architecture (see Figure 8b) does away with the ATM layer by having the SONET payload directly carry IP datagrams that have been encapsulated by PPP in HDLC encoding. However, this approach requires the use of byte stuffing to enable the receiver to detect the

Figure 8: Multilayer network architectures

start of the HDLC frame. In addition, it requires the use of three separate management layers.

The best approach is to do away with the SONET layer completely and send the IP data directly over the DWDM optical layer (see Figure 8c). Thus, only two management layers are needed. Multiprotocol Label Switching (MPLS) is used as the adaptation layer between the IP and the optical layer to provide traffic engineering. By using wave-lengths in place of labels, the IP traffic can be routed over the DWDM infrastructure. An extension to MPLS, called generalized MPLS (GMPLS) has been developed to support such a capability (see Generalized Multiprotocol Label Switching) (Gallaher, 2002).

Generic Framing Procedure

Two new encapsulation approaches for carry packet data over a SONET/SDH network have been developed by the ITU-T: generic framing procedure (GFP) and G.709. GFP (ITU G.7041/Y.1303) provides a generalized mechanism for enabling SONET/SDH networks to carry any type of packet data (Bonenfant and Rodriguez-Moral, 2002; International Telecommunication Union, 2005; Scholten et al., 2002). GFP specifies an efficient procedure for mapping both framed packet data such as IP in PPP and Ethernet, and block code oriented data such as enterprise system connect (ESCON), fiber connection (FICON), and fiber channel (FC) onto multiple concatenated STS-1 SPEs in a SONET/SDH frame. GFP also supports the multiplexing of diverse client data traffic over a DWDM wavelength.

The GFP frame format consists of a core header, a payload header, the client payload data, and a payload CRC (Figure 9). The core header contains a two-byte payload length and a two-byte core header error control (cHEC) field. The cHEC is a 16-bit CRC that is used for header error detection. The core header is also used for frame boundary delineation (i.e., frame synchronization). GFP frame delineation requires the correct detection of two consecutive cHECs.

The payload header contains the payload type and type header error control (tHEC) fields. The payload type field specifies whether the payload field contains user data or management information. For user data, the user data

identifier field indicates the specific data type being carried by the GFP frame.

GFP support two transport modes: frame mapped GFP (GFP-F) and transparent mapped GFP (GFP-T). GFP-F is optimized for packed switched data such as IP, PPP, Ethernet, and MPLS data. GFP-F supports rate adaptation and multiplexing at the packet level and aggregates the frames at the STS level. Because frames must be buffered, latency is introduced into the data stream.

The GFP-T mode is optimized for data traffic that is delay sensitive such as FC, FICON, and ESCON. GFP-T operates on fixed length frames in real time. Because there is no buffering of the data traffic, no latency is introduced into the data stream.

G.709

In 2003, the ITU-T specified the G.709 protocol to enable packet data to be transported reliably and efficiently over optical fiber networks. It is a more efficient protocol for carrying packet data than the voice-centric SONET/SDH standard. It enables the transparent transport of client signals. In addition, it adds an optical channel layer for managing all of the wavelengths on a fiber in a DWDM network by wrapping each wavelength in a digital envelope (Bonenfant and Rodriguez-Moral, 2001; International Telecommunication Union, 2003).

The G.709 digital envelope consists of a header in which the overhead bytes are carried and a trailer that contains forward error correction (FEC) bytes (Figure 10). The header provides operations, administration, maintenance and provisioning (OAM&P) data for managing the optical network. The FEC bytes are used to detect and correct errors in the payload. G.709 uses the FEC specified in the ITU-T G.975 standard. It provides up to 5.6 dB improvement in the signal to noise ratio (SNR). The use of FEC enables either a longer span length or a higher bit rate for a SONET/SDH network, or more wavelengths to be carried over a DWDM network.

The G.709 frame consists of 4080 columns by 4 rows of bytes for a total of 16320 bytes. Unlike SONET/SDH the frame size is fixed; higher data rates are realized by an increase in the data rate of the channel. Thus, G.709 is no

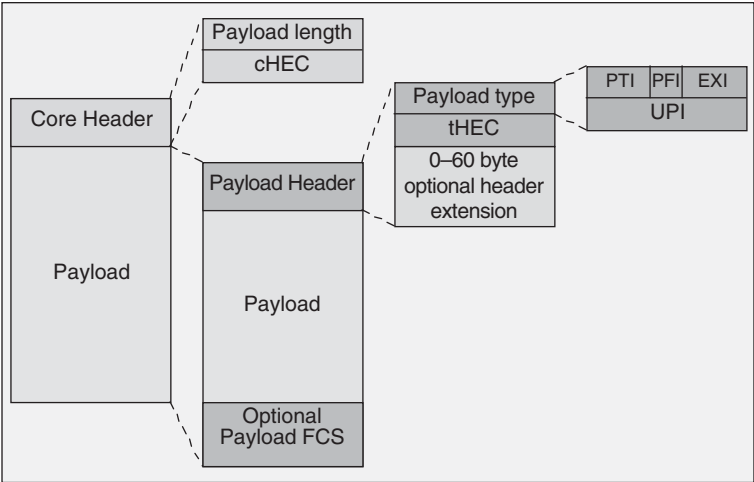

Figure 9: GFP frame format

Figure 10: G.709 frame format

longer tied to the 8-KHz data rate used by SONET/SDH and other circuit switched protocols.

The G.709 frame header contains a frame alignment field, optical channel transport unit (OTU) overhead field, optical channel data unit (ODU) field and an optical channel payload unit (OPU) field. The frame trailer contains a Reed-Solomon (255,239) FEC. For every 239 bytes of data an additional 16 bytes of overhead is added for error detection and correction. The FEC can detect up to 16 symbols in error and correct up to eight symbol errors in the code.

G.709 defines three standard OTU interfaces that support data rates of 2.666, 10.709, and 43.018 Gbps for transporting STM-16, STM-64, and STM-256 payloads respectively. G.709 is protocol independent; the digital wrapper encapsulates a payload that can map SONET/SDH, Ethernet, ATM, IP, MPLS, and GFP protocols.

MAN STANDARDS

Initially, the IEEE 802 committee had limited its standardization efforts to LANs. The original IEEE 802 charter restricted the data rates for networks to a maximum of 20 Mbps. Beginning in 1980, the 802 committee developed standards for Ethernet (802.3), token bus (802.4), and token ring (802.5) LANs. However, the committee members soon saw a need for a network that provided higher speeds and spanned longer distances than LANs. Thus, the artificial restriction on speed was removed, and the 802 committee commenced the development of standards for MANs.

The initial standard for a fiber based distributed queue dual-bus MAN was developed by the 802.6 Working Group in 1987. Subsequently, the IEEE 802 committee developed two additional standards for MANs. In 1999, the 802.16 Working Group began the development of standards for fixed broadband wireless access MANs, and in 2001, the 802.17 Working Group commenced the development of a standard for a fiber-based resilient packet ring MAN.

IEEE 802.6 DQDB

In 1981 the IEEE 802.6 Working Group began the development of a high-speed MAN standard that would go beyond the boundaries of a LAN. The Working Group's requirement for a MAN was that it must support both voice and data; thus in addition to best effort packet transfer, it must provide a guaranteed bandwidth with a bounded delay. The resulting 802.6 standard for a distributed queue dual

bus (DQDB) MAN was completed in 1987 (Institute of Electrical and Electronics Engineers, 1990).

A DQDB MAN consists of a head station, two unidirectional buses, access units, and an end station. The access units attach to both buses via read/write connections. The DQDB is implemented as a looped-bus topology that is physically a ring but acts logical as a bus. The end points are collocated so that one DQDB node serves as the master frame generator for both buses. Because data do not flow through the head point of the loop, it is not necessary to remove data from the medium as with a ring. Another benefit of the loop bus architecture is that it provides redundancy. If a node or a link fails, the network can close the data buses through the head point of the loop to enable the network to continue to function.

The basic unit of data transfer on a DQDB MAN is the 53-octet slot (Figure 11). A slot is the same size as an ATM cell. It consists of a 1-octet header called the access control (AC) field and a 52-octet segment field. The AC field contains the busy and request bits that control access to the medium.

DQDB Operation

The DQDB MAC protocol controls user access to the network. A single distributed queue is established for all of the nodes on each bus. Each node has a request (RQ) counter and a countdown (CD) counter. The node keeps track of the number of segments queued downstream from itself by counting the request (REQ) bits as they pass on the reverse bus. Each REQ passing on the reverse bus causes the RQ counter to be incremented. An empty segment that passes the node is used by a downstream node to transmit one of the segments that it has already queued. The RQ counter is decremented each time an empty slot passes on the forward bus. Thus the RQ counter keeps an exact count of the number of segments queued downstream.

Figure 11: DQDB slot

To send data over the bus, the node transfers the current value of the RQ counter to its CD counter. The segment to be transferred is placed in the distributed queue by loading the CD counter with the number of downstream segments queued ahead of it (from the RQ counter), resetting the RQ counter, and sending a REQ over the reverse bus. The CD counter is decremented for every empty slot that passes on the forward bus. When the CD counter goes to zero, the node transmits its segment in the next empty slot that passes it. Any new requests received by the node after the CD counter is set are used to increment its RQ counter. Thus, the RQ counter tracks the current number of segments that have been queued by the downstream stations for its next transmission. Priority queuing is achieved by operating a separate distributed queue for each of the three levels of priority.

Data Transfer

In order to transfer data over a DQDB network using the connectionless MAC service, it is necessary to break the data into pieces that can fit into the DQDB slot. The MAC convergence function carries out the segmentation and reassembly of the data sent to it by the LLC layer. It accepts a MAC service data unit (SDU) from a DQDB user, segments it, and transmits it to the destination. The DQDB layer at the destination reassembles the segments into the original data and sends it to the user of the service. Before segmentation takes place, the MAC SDU is encapsulated with a header and a trailer to form an initial media access control protocol data unit (IMPDU). The IMPDU header contains the source and destination addresses of the data and a beginning-end tag that is matched against the beginning-end tag in the IMPDU trailer at the destination to check that all of the data was received (Figure 12).

The IMPDU is then divided into 44-byte segmentation units that are encapsulated with a two-byte header and a two-byte trailer to form a derived media access control protocol data unit (DMPDU). The DMPDU header consists of a 2-bit segmentation type, a 4-bit sequence number,

and a 10-bit message identifier. The segmentation type indicates if the DMPDU is the first, middle, or last segment of the IMPDU. The sequence number is used to check for missing pieces of the data. The message identifier allows the destination station to separate fragments from multiple IMPDUs that are being sent at the same time.

The DMPDU trailer consists of a 6-bit payload length and a 10-bit payload cyclic redundancy check (CRC). The length field indicates the actual size of the data in the fixed size segment. The CRC checks for errors in the DMPDU.

The DQDB protocol provides excellent performance. If no segments are waiting, access to the bus is immediate. The node is able to transmit on the next empty segment that passes it. Also slots are never wasted if data is queued for transmission. The protocol guarantees a minimum access delay at all levels of loading right up to the maximum network utilization of 100%. The protocol also supports fair access to the bus. To prevent one node from grabbing all of the bandwidth, a node cannot make a second request until the first request is satisfied.

IEEE 802.17 Resilient Packet Ring

In 2003, the IEEE 802.17 Working Group completed the development of a new fiber-based standard for MANs. The resilient packet ring (RPR) is a high-speed network that is optimized for packet transmission (Institute of Electrical and Electronics Engineers, 2004b). As the name indicates, RPR is a ring-based network that comprises a dual set of counter-rotating rings. Each station on the ring is connected to its upstream and downstream neighbors by P-P links. The dual-ring architecture allows for resiliency; the network can recover from a break in one of the rings by wrapping the two rings together to bypass the failed link.

Unlike SONET/SDH rings, RPR provides a mechanism for using the full bandwidth of both rings for the transmission of data. SONET/SDH rings also consist of a dual counter-rotating ring configuration, but one of the rings is used solely for backup. With RPR it is not necessary to set aside half of the bandwidth for backup. In order to allow the full bandwidth to be used for data transmission, a fairness algorithm and a prioritization mechanism are specified so that higher priority data can be given preference. An auto-restoration capability is specified to enable the reconfiguration of the ring in the event of a link failure.

RPR Operation

RPR consists of two unidirectional counter-rotating rings. The outer ring is called ringlet 0 and the inner ring is called ringlet 1. Each station on the ring is given a standard 48-bit MAC address. The station with data to send to another station decides which of the two rings to use to send the data. Thus, RPR allows the shortest path between stations to be selected for the transmission of data. Each station on the path between the source and destination station forwards the frame to the next station (Yuan, Gambiroza, and Knightly, 2004).

Unlike the token ring protocol, when the destination station receives a unicast frame, it removes it completely from the ring rather than just copying it and sending it back to the source station. This technique enables the

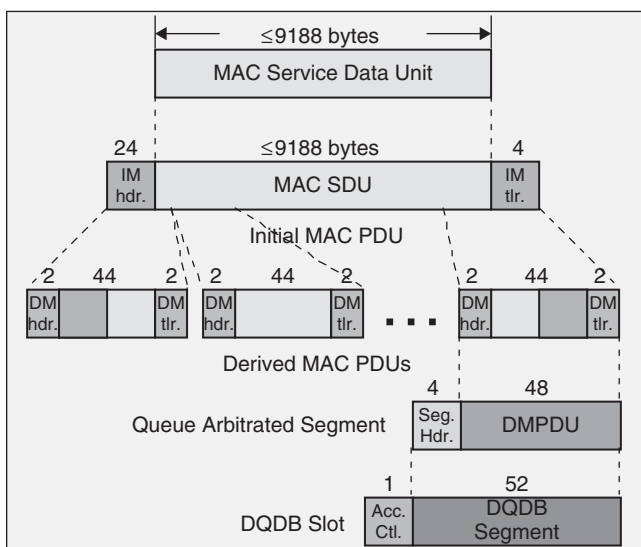

Figure 12: Data encapsulation and segmentation

Figure 13: Spatial reuse in an RPR network

ring to be used more efficiently because it allows for spatial reuse of the bandwidth. The bandwidth that would have been used by the frame as it traveled back to the source station is now used by another station to send data. Thus, multiple stations can send data simultaneously over non-overlapping portions of the ring. This is called spatial reuse. As shown in Figure 13, station S1 is sending data to station S4 at the same time that station S5 is sending data to station S7.

To prevent a frame from circulating forever, a time to live (TTL) field is included in the frame header. The TTL is decremented each time the frame arrives at a station on the ring. When the TTL value goes to zero, the station removes the frame from the ring.

Like all of the IEEE 802 standards, RPR encompasses the data link and the physical layer of the ISO reference model. The data link layer comprises two parts: the logical link control (LLC) sublayer that is common to all IEEE 802 LAN and MAN protocols and the MAC sublayer that contains the control logic for the RPR protocol. The MAC sub-layer, in turn, contains two parts: MAC control and MAC data path. The MAC control sub-layer controls the transfer of data between the MAC and its LLC client. The MAC datapath sub-layer provides data transfer functions for each ringlet.

The physical layer contains a reconciliation sub-layer and the physical layer protocol (PHY). Two Packet PHYs and a SONET/SDH PHY are specified in the RPR standard. The Packet PHYs are based on the 1 Gbps and the 10 Gbps-Ethernet PHYs. The SONET/SDH PHY supports data rates from 155 Mbps to 10 Gbps.

Classes of Service

The RPR data transfer service is controlled by two parameters: a committed information rate (CIR) and an

excess information rate (EIR). RPR specifies three different service classes for data transfer. Class A service is for delay sensitive (real time) traffic. Class B service provides for the transfer of traffic with bounded delay (near real time). Class C provides a best effort data transfer service (see Table 1) (Davik et al., 2004).

Class A traffic is allocated with a CIR. It provides a guaranteed data rate and a low end-to-end delay and jitter. There is a maximum amount of Class A traffic that can be allocated; traffic above this allocated rate is rejected. Class A traffic has precedence over Class B and Class C traffic. Also, Class A traffic is not subject to the fairness algorithm; thus class A traffic will not be discarded by the RPR. Class A service consists of two subclasses: subclass A0 and subclass A1. Unused subclass A1 bandwidth can be reclaimed for use by class B-EIR and class C traffic.

Class B service also consists of two subclasses: Class B-CIR and Class B-EIR. Class B-CIR traffic is allocated with a CIR and provides bounded MAC end-to-end delay and jitter for the amount of traffic within the profile of the CIR. For data rates between CIR and EIR, Class B-EIR provides a best effort service.

Class C traffic provides a best-effort traffic service with no allocated or guaranteed data rate and no bounds on the end-to-end delay or jitter. Both Class B-EIR and Class C traffic is marked as fairness eligible. Fairness eligible traffic uses bandwidth that is available from the unallocated bandwidth and the unused reclaimable bandwidth. Thus Class A1 and Class B-CIR allocated bandwidth that is not being used can be reclaimed by a lower priority Class B-EIR or Class C station if it does not impact the service guarantee for the higher priority service class stations.

A weighted fairness algorithm is used to allocate bandwidth among the Class B-EIR and Class C stations. The fairness algorithm is used to prevent congestion on the

Table 1: RPR Classes of Service

Class of Service			Quality of Service				Fairness Eligible
Class	Type of Use	Subclass	Guaranteed Bandwidth	Jitter	Type	SubType	
A	real-time	SubclassA0	yes	low	allocated	reserved	no
		SubclassA1	yes	low	allocated	reclaimable	
B	near real-time	classB-CIR	yes	bounded	Opportunistic	reclaimable	yes
		classB-EIR	no	unbounded			
C	best effort	—					

ring. The algorithm calculates a fair rate for all of the stations with fairness eligible traffic.

G.709 with IEEE 802.16 WirelessMAN

The IEEE 802.16 Working Group is developing standards for fixed and mobile broadband wireless access (BWA) systems. The standards have been given the trademark name WirelessMAN by the 802.16 Working Group. The purpose of WirelessMAN is to provide an alternative to the fiber-based broadband access systems that have been implemented in metropolitan areas. The 802.16 standards support a point-to-multipoint topology in which a network base station (BS) communicates with a large number of subscriber stations (SSs). The network BS provides the SSs with connectivity to the wired public network.

The original 802.16 specification, published in April 2002, provided a LOS capability for fixed broadband wireless access in the licensed 10–66 GHz portion of the RF spectrum. Data rates of 120 Mbps or more can be achieved using channel bandwidths of 25–28 MHz. A revised version of the IEEE 802.16 air interface standard was published in 2004 (Institute of Electrical and Electronics Engineers, 2004a).

The 802.16 specification was followed by the 802.16a specification (published in April 2003), which added non-LOS BWA for both the licensed and the license-exempt bands in the 2–11 GHz portion of the RF spectrum. Changes were made to the 802.16 physical layer to support near-LOS and non-LOS (NLOS) signals. These changes include advanced power management techniques, interference mitigation, and the use of multiple antennas to process multipath signals.

The latest WirelessMAN standard, 802.16e, was published in December 2005. It adds a mobile capability to the WirelessMAN standard by allowing handovers to take place between BSs for SSs moving at vehicular speeds in the under 6 GHz licensed bands (Institute of Electrical and Electronics Engineers, 2005). The 802.16e standard specifies a system for a combined fixed and mobile BWA. It supports handovers between BSs managed by the same and different access control sites. In addition, it specifies an inter-technology mobility function that allows for handovers between IEEE 802.16e, WiFi, and 2.5G/3G networks.

MAC Functionality

The IEEE 802.16 standard specifies the MAC and PHY protocols for a high-speed wireless MAN. A common MAC protocol is specified across both frequency bands; however different PHYs are specified for each of the bands and for the licensed and unlicensed frequency bands. The MAC layer controls the transfer of data over the PHY and provides functions for authentication, association, and dissociation of the user devices. Both frequency division duplexing (FDD) and time division duplexing (TDD) are used to provide full duplex transmission for the uplink and downlink channels (Eklund et al., 2002).

The WirelessMAN MAC comprises three sublayers: the service-specific convergence sub-layer (CS), the MAC common parts sub-layer (CPS) and the security sub-layer. The CS maps external data formats into MAC service data

units (SDUs) and associates the external SDUs to the proper MAC service flow identifier (SFID) and connection identifier (CID). In addition it may include payload header suppression (PHS). The CPS provides the basic MAC functionality of system access, bandwidth allocation, connection establishment and connection maintenance. The security sub-layer provides authentication, secure key exchange, and encryption.

Two CS specifications are provided: the asynchronous transfer mode (ATM) and the packet CS. The ATM CS accepts ATM cells from the ATM layer, classifies them, and if chosen, provides payload header suppression. The ATM CS PDU consists of an ATM CS PDU header and the ATM CS PDU payload. If no payload header suppression is being used then the ATM CS PDU header is the normal ATM cell header. The packet CS is used to transport all packet-based protocols including IP, PPP, and IEEE 802.3/Ethernet.

OFDM

The IEEE 802.16e standard specifies the use of both orthogonal frequency division multiplexing (OFDM) and orthogonal frequency division multiple access (OFDMA) technologies to transmit high-speed data over the air interface. OFDM is a form of frequency division multiplexing where a channel is divided into a large number of sub-channels and a portion of the data is sent over each of the sub-channels (Flarion Technologies, Inc., 2003). With OFDM, the frequencies used for each sub-channel are selected to be orthogonal. Orthogonal means that there is no interference between adjacent sub-channels because the main lobe of each carrier lies on the null of the other carriers (Figure 14). The orthogonal nature of OFDM allows the sub-channels to overlap, thus increasing the spectral efficiency of the channel. The 802.16e PHYs support 256, 1024, or 2048 sub-channels.

OFDM is an optimum solution for communicating in a NLOS environment where there is selective fading as a result of multipath propagation. The 802.16e standard specifies the use of quadrature phase shift keying (QPSK), 16-level quadrature amplitude modulation (16-QAM) or 64-QAM adaptive modulation techniques for the individual sub-channels to increase the spectral efficiency of these sub-channels. Up to 3.75 bps/Hz of bandwidth (2 bps/Hz average) can be achieved using this technique.

OFDMA

In order to share the bandwidth among the network subscribers, the 802.16e standard specifies the use of a scalable OFDMA scheme. OFDMA is a combination of a modulation and an FDMA and TDMA multiple access scheme. It divides the available OFDM sub-carriers into logical groups called sub-channels (Yaghoobi, 2004).

Figure 14: OFDM tones

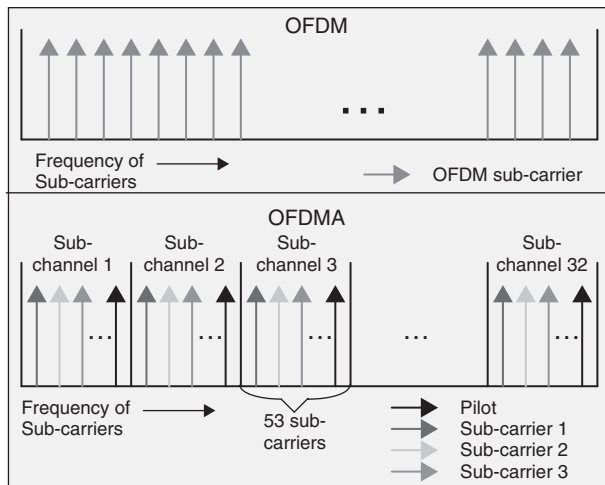

Figure 15: OFDMA channel partitioning scheme

For example, the 2048 sub-carrier uplink scheme specified in the 802.16e standard uses 1696 sub-carriers for data. The rest of the sub-carriers are used for guard bands and pilots. The 1696 sub-carriers are divided into 32 sub-channels that consist of 53 sub-carriers each (Figure 15). Coding, modulation, and amplitude can be separately set for each sub-channel to optimize the use of network resources. Multiple SSs can simultaneously access the channel by transmitting on different sub-channels. SSs are allocated one or more of the sub-channels for each transmission burst. By dynamically assigning the number of sub-channels, OFDMA provides a flexible means to allocate the capacity of the channel to the current SSs.

Because each SS concentrates its output power only on a portion of the channel bandwidth the signal to noise ratio (SNR) at the receiver is increased. If 32 SSs each transmit on one of the 32 sub-channels, there would be a 15-dB improvement in SNR on the channel. To provide support for asymmetric traffic rates for the upstream and downstream paths over the air interface, a time division duplex (TDD) scheme is specified. However, a frequency division duplex (FDD) scheme is also supported.

The 802.16e standard allows the bandwidth of the radio channel to be specified in multiples of 1.5 MHz (U.S.) or 1.75 MHz (Europe). To meet the needs of both urban and rural environments the standard supports variable bandwidth sizes between 1.5 and 20 MHz for NLOS operations. However, neither OFDM nor OFDMA (without scalability) can meet the performance requirements for all of these bandwidths for vehicular operation in a multipath fading environment without the use of a scalable OFDMA scheme. With scalable OFDMA, the fast Fourier transform (FFT) size scales with bandwidth to keep the sub-carrier spacing fixed. Scalable OFDMA enables the 802.16 standard to provide optimum performance for both a fixed and a portable/mobile communications environment.

It would appear that the 802.16e standard for mobile BWA duplicates capabilities provided by existing 2.5G/3G cellular standards and the draft IEEE 802.20 mobile broadband wireless access (MBWA) service. The optimistic

view is that 802.16e will complement existing IP Internet access services provided by the 2.5G/3G cellular networks, WiFi, and the draft IEEE 802.20 MBWA service. A more realistic view is that it will compete with the existing and planned cellular network IP data services.

IEEE 802.20

In December 2002 the IEEE 802 committee approved the formation of the IEEE 802.20 MBWA Working Group (WG). The objective of the 802.20 WG is to develop a specification for the physical and medium access control layers of an air interface for a mobile broadband wireless access network that is optimized for the transport of IP based services. The air interface would operate in the licensed bands below 3.5 GHz and support peak data rates per user in excess of 1 Mbps at vehicular speeds up to 250 km/h in a MAN environment (Klerer, 2003).

The original intent of the 802 committee was for the 802.20 standard to fill the performance gap that existed between the 802.16 high data-rate low mobility services and the high mobility cellular networks. However that was before the 802.16 WG developed the 802.16e specification that added a mobile capability to the 802.16 standards.

Although both 802.16e and the cellular 2.5G/3G networks also support mobility, the 802.20 WG insists that 802.20 provides different capabilities than each of these networks. With respect to the cellular networks, the WG argues that 802.20 is being developed as a “pure IP” network that does not have the legacy issues of supporting circuit switched services. Also, because 802.20 is being designed to operate in the same frequency band as the 2.5G/3G cellular networks it will be able to coexist with the infrastructure of these cellular networks.

With respect to the 802.16e standard, the 802.20 WG argues that 802.20 was designed from the beginning for mobility and not as a mobile enhancement to a fixed broadband wireless network. In addition the WG states that 802.20 will support higher vehicular speeds (250 km/h vs. 120 km/h) than the 802.16e standard and it will operate in the licensed frequency bands below 3.5 GHz as opposed to the 2 to 6 GHz frequency range for 802.16e.

At the time of the writing of this chapter (June 2006), the IEEE-SA Standards Board directed that all activities of the 802.20 WG be temporarily suspended. The reason given was to enable the board to deal with contention that had arisen among the members and “irregularities” in the operation of the 802.20 WG. The suspension will continue until October 1, 2006 to give the board time to address these problems.

European Standardization Activities

The European Telecommunications Standards Institute (ETSI) has commenced the broadband radio access network (BRAN) standardization effort for the purpose of developing broadband wireless access (BWA) standards. The BRAN standards will cover the physical and data link layers of the OSI 7-layer model for network communications. The BRAN Working Groups are focusing on standards for high-speed (≥ 25 Mbps) broadband wireless communication that uses the GHz portion of the RF

spectrum. In order to provide a set of standards that will be universally accepted, ETSI is working closely with the IEEE 802.16 Working Group to develop interoperable standards for BWA.

BRAN has developed two standards for the GHz portion of the RF spectrum. High performance radio access (HIPERACCESS) is a P-MP wireless access network that provides communications channels in the upper part of the millimeter portion of the RF spectrum (11–42 GHz). High performance radio metropolitan area network (HIPERMAN) is also a P-MP wireless access network that uses the 2–11 GHz portion of the RF spectrum.

HIPERACCESS

HIPERACCESS network deployments will consist of a number of cells. Each of the cells will cover a portion of a metropolitan area. The cells will have a P-MP topology in which a network base station communicates with multiple subscriber sites. The cell can be partitioned into a small number of sectors with a maximum of 256 subscriber sites per sector. As a result of the high frequencies used, LOS transmission is used and the distance covered is limited to a few kilometers. Either FDD or TDD duplex schemes can be used for the uplink and downlink paths (European Telecommunications Standards Institute, 2002).

The modulation scheme used for HIPERACCESS is QAM. A Reed-Solomon (R-S) code that is concatenated with a convolutional code, with no interleaving, is employed for forward error correction. In the downlink direction, data sent to different subscriber sites is multiplexed in the time domain. Because HIPERACCESS employs adaptive PHY modes, different TDM groupings can be assigned different PHY modes.

In the uplink direction the subscriber stations use time division multiple access (TDMA) to share the RF channel. The channel spacing in both the uplink and downlink directions is 28 MHz with a maximum capacity of 60-Mbps downlink and 30-Mbps uplink.

HIPERMAN

The HIPERMAN standard is designed for fixed wireless access for small to medium size business and residential locations. HIPERMAN operates in the 2 and 11 GHz frequency spectrum. The communications environment is one in which there is NLOS communications; therefore HIPERMAN equipment must operate in the presence of multipath. HIPERMAN supports a P-MP topology and optionally a mesh topology. HIPERMAN was designed to be a subset of the IEEE 802.16a standard. It uses the 802.16a MAC layer; thus it supports the MAC layer QoS, packing, and fragmentation functions. HIPERMAN provides an aggregate throughput of 25 Mbps (European Telecommunications Standards Institute, 2005).

The PHY layer uses the OFDM modulation scheme with a 256-point transform. TDD is used for communications in the uplink and downlink directions. The HIPERMAN FEC scheme consists of an R-S outer code and a rate-compatible convolutional inner code. The channel bandwidths used can vary from 1.5 to 28 MHz. The standard is optimized for radio systems in the 3.4- to 4.2-GHz frequency band.

MAN IMPLEMENTATIONS

In response to the needs for a high-speed networking capability and more and more bandwidth in the metropolitan area, the local telcos installed a large number of SONET/SDH rings. SONET/SDH provided a means for multiplexing the existing slower speed telco T1/E1 digital circuit offerings onto a higher speed circuit. Although SONET/SDH was able to provide the bandwidth and reliability mechanisms needed to implement a high-speed MAN, it did not provide any native QoS features and provisioning of new customer circuits was a very slow and difficult process.

To address these problems the telcos implemented the standards-based switched multimegabit data service (SMDS). SMDS provides a capability to directly carry high-speed LAN traffic between customer sites. In addition, it provides a prioritization scheme based upon the IEEE 802.6 standard that enable the telcos to offer customers different levels of QoS.

Another approach taken by the telcos to meet the need for bandwidth in the metropolitan area was the use of DWDM to increase the capacity of existing and new fiber by two or more orders of magnitude. DWDM enabled the telcos to meet their customers' needs for bandwidth and QoS by providing them with an individual wavelength on the fiber that is dedicated to their data traffic.

An example of a DWDM MAN is the Komnet network in Berlin. As shown in Figure 16, the network consists of two dual DWDM rings. Each ring has a diameter of 60 km and contains 80 wavelengths. Access to the rings is through optical add-drop multiplexers. The rings are connected to Frankfurt by a long-haul WDM link. IP over WDM is used to transport Internet data over the DWDM rings. High-end users can use Gigabit Ethernet or SONET/SDH to transmit data onto the rings.

The latest approach taken by the telcos for implementing MANs is to provide their customers with a Metro Ethernet networking capability. Because Ethernet is the underlying communications technology for almost all data traffic at a customer's site, the idea is to simply provide a means to carry the Ethernet traffic directly over a MAN. However a major obstacle that must be overcome in order to make Metro Ethernet MANs as popular as Ethernet LANs is to be able to provide QoS mechanisms that are lacking in the Ethernet protocol.

SONET/SDH Rings

The Synchronous Optical Network (SONET) standard was developed by the T1 committee of the American National Standards Institute (ANSI). The initial SONET standard was complete in 1988. SONET was originally proposed by Bellcore (now Telcordia) in the mid-80s to replace the existing PDH transport hierarchy for digital data (American National Standards Institute, 1995). Development of the Synchronous Digital Hierarchy (SDH) was carried out at the same time by the International Telephone and Telegraph Consultative Committee (CCITT; now the International Telecommunications Union-Telecommunications Standardization Sector [ITU-T]) (International Telecommunication Union, 2000). SONET and SDH are similar but not identical standards as a

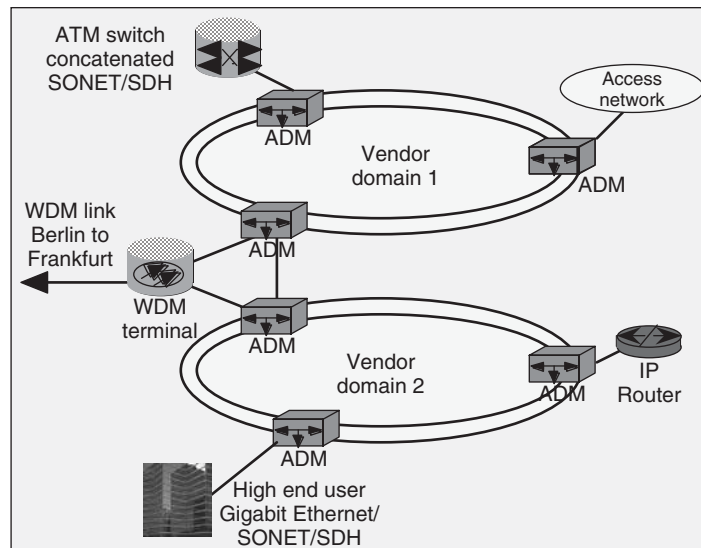

Figure 16: KomNet DWDM MAN

result of the need to accommodate the different digital data rate hierarchies that existed in the United States and Europe. However, the desire to have compatible worldwide optical standards led to a series of compromises that set the basic data rate of the SONET STS-1 circuit (51.84 Mbps) to be exactly one-third the rate of the SDH STM-1 circuit (155.52 Mbps).

Multiplexing Hierarchy

SONET/SDH is an interface specification for an optical transmission system. The specification defines the frame structure for carrying digital data and provides a standardized hierarchy of multiplexed digital transmission rates that accommodate existing North American and European data rates. It establishes an optical signal standard for interconnecting equipment from different suppliers along with extensive operational, administrative, maintenance, and procedural (OAM&P) functions to monitor and control the optical network.

The SONET specification defines an hierarchy of standardized digital data rates that are multiples of the basic synchronous transport signal level 1 (STS-1) rate of 51.84 Mbps. SDH defines a similar data rate structure based on multiples of the basic synchronous transport module 1 (STM-1) data rate of 155.52 Mbps (Table 2).

Table 2: SONET/SDH Multiplexing Hierarchy

SONET	SDH	Optical level	Line Rate (Mb/s)	Payload Rate (Mb/s)
STS-1	STM-0	OC-1	51.84	50.112
STS-3	STM-1	OC-3	155.52	150.336
STS-12	STM-4	OC-12	622.08	601.344
STS-48	STM-16	OC-48	2488.32	2405.376
STS-192	STM-64	OC-192	9953.28	9621.504
STS-768	STM-256	OC-768	39813.12	38486.016

The SONET/SDH standards also specify the method for multiplexing existing lower speed digital signals into a SONET/SDH frame. STM-1 is divided into a payload structure called virtual containers (virtual tributaries [VTs] in SONET). Three types are specified to support sub DS-3 (44.736 Mbps) data rates: VC-11 supports T-1 signals (1.544 Mbps), VC-12 supports E-1 signals (2.048 Mbps), and VC-2 supports DS-2 signals (6.312 Mbps). A set of rules specifies how these VCs and VTs can be packed into the STM-1 and STS-1 signals, respectively.

The basic SONET building block is the STS-1 frame (Figure 17). It consists of 810 bytes that are transmitted once every 125 μ s (8000 Hz) for a data rate of 51.84 Mbps. (The basic STM-1 frame contains 2430 bytes.) The frame can be logically viewed as a matrix of 90 columns by 9 rows. Data transmission takes place one row at a

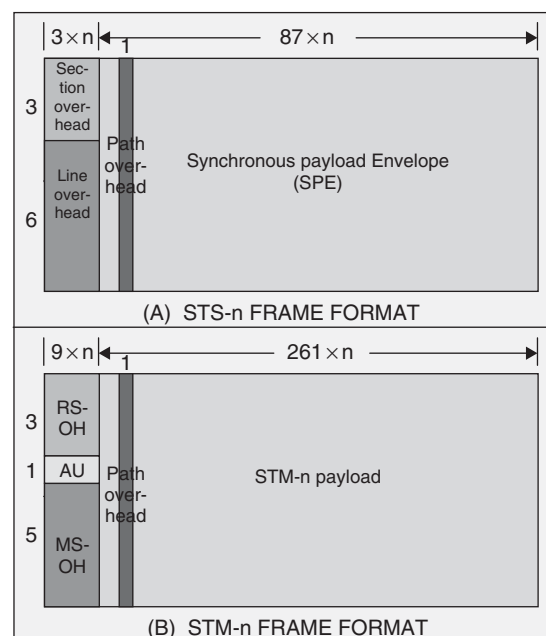

Figure 17: SONET and SDH frame format

time, from left to right and top to bottom. The first three columns (3 bytes \times 9 rows = 27 bytes) of the frame are devoted to overhead bytes. Nine bytes are section-related overhead and 18 bytes are line-related overhead. The remainder of the frame is payload. The payload includes a column of path overhead. The line overhead contains a pointer that indicates where the path overhead starts in the payload field (Goralski, 2002).

SONET provides a drop and insert capability. It makes use of a set of pointers that locate channels within a payload and the entire payload within a frame. This allows data to be accessed, inserted, and removed with a simple adjustment of pointers. The pointer information pertaining to the multiplex structure of the channels in the payload is in the path overhead. A pointer in the line overhead serves the same purpose for the entire payload. The synchronous payload in an STS-1 frame floats with respect to the frame. Thus, the actual payload (87 columns \times 9 rows) can cross a frame boundary. The H1 and H2 bytes in the line overhead are used to indicate the start of the payload.

Ring Topologies

A ring provides a simple mechanism for constructing a resilient network. A dual counter rotating SONETSDH ring architecture provides a fault tolerant and flexible transmission capability that is used to implement a self-healing network. If a break occurs in one of the rings, the traffic can be sent over the second ring to provide an automatic backup capability. Also if there is a break in both rings, a complete transmission path can be constructed by wrapping the rings together. This enables data to be sent to any node on the ring.

A SONET/SDH ring is constructed by connecting together a number of network nodes using P-P optical fiber links to form a closed path. The network nodes can be add-drop multiplexers (ADMs) or digital cross connects (DCSs). The ADMs allow traffic to be added and removed from the ring. The standards organizations have defined three types of SONET/SDH self-healing rings: a unidirectional path switched ring (UPSR), a two-fiber bidirectional line switched ring (BLSR2), and a four-fiber bidirectional line switched ring (BLSR4) (Goralski, 2002). Figure 18 shows the UPSR, BLSR2, and BLSR4 ring topologies.

Each of these ring networks is composed of a set of nodes that are connected together by optical fiber links that form counter-rotating rings. Access to the network is through ADMs that multiplex and demultiplex tributary traffic onto and off of the optical rings using time division multiplexing (TDM). In order to restore communications rapidly in the event of a link or node failure, half of the capacity of the ring is reserved for backup. When a failure occurs the traffic is switched onto the reserved ring capacity. Switching can be done rapidly (on the order of 50 ms) because the automatic protection switching bytes in the SONET header can signal a ring failure in real time.

A UPSR network (see Figure 18a) is composed of two counter-rotating rings, a working ring and a protect ring. The working ring is used to carry user traffic from node to node in one direction. The protect ring is also used to carry the same user traffic between the nodes in the other

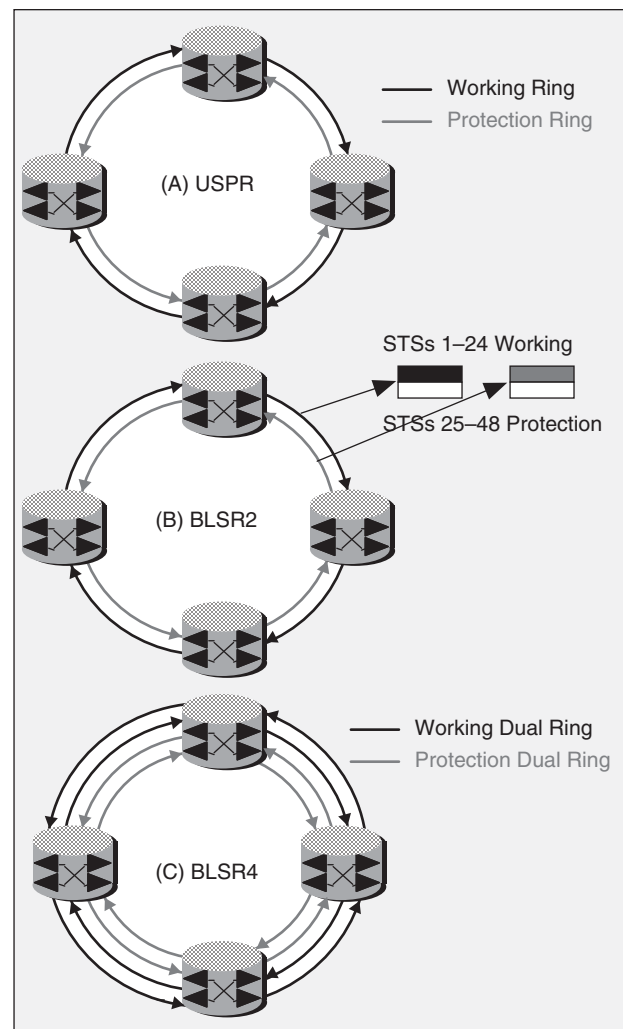

Figure 18: UPSR, BLSR2, and BLSR4 SONET ring topologies

direction. Unless the protect ring has a better signal quality, only the working ring is used to transmit the data. If there is a link failure on the working ring, the protect ring is then used to transmit the data.

The BLSR2 network (see Figure 18b) also has two counter-rotating rings. Each fiber pair between two of the nodes is treated as a full-duplex link. However only half of the capacity of the fiber is used for transmitting data; the other half is used for protection. If there is a single link failure, the data is looped back around the ring using the protection bandwidth of the other links. The advantage of BLSR2 over UPSR is that by having a full duplex path, the data can be sent over the shortest path between the nodes. Also, the bandwidth can be reused around the ring.

The BLSR4 network (see Figure 18c) has two pairs of counter-rotating rings. One pair is used for the transfer of working traffic and the other pair is used for protection. Thus, BLSR4 provides double the capacity of the BLSR2 and the UPSR rings. BLSR4 increases the reliability and flexibility of traffic protection because it allows for both span switching and ring switching. Span switching occurs when a working span fails. The traffic is switched to the protect fibers only between those same pair of nodes. The traffic returns to the working fibers for the rest of the

nodes. Ring switching occurs when both the working and protect link between a pair of nodes fails. To recover from a complete link failure, traffic is looped back through the protect fibers throughout the full ring.

Switched Multimegabit Data Service

Switched multimegabit data service (SMDS) was developed by Bell communications Research (Bellcore), the research arm of what was then the seven Bell Operating Companies (BOCs). Bellcore (now Telcordia) was formed as a result of the divestiture of the local phone companies from AT&T as part of the settlement of the 1984 antitrust lawsuit by the Justice Department. The SMDS service was aimed at supporting LAN interconnection and other data communications applications that require LAN-like performance across a metropolitan area. SMDS is based on the IEEE 802.6 MAN standard. It uses an underlying cell switching technology that is similar to ATM (both use a 53-octet cell) and the 802.6 DQDB media access control technique.

SMDS Operation

SMDS supports LAN interconnection through the encapsulation of LAN frames in SMDS packets. The encapsulation and decapsulation is performed by routers at the edges of the SMDS network. Because up to 9188 bytes can be sent in a single data transfer, SMDS provides the user with a high-speed subnet for the transparent transfer of any type of LAN data packets (e.g., Ethernet, token ring, FDDI).

User access to the SMDS network is over the SMDS subscriber network interface (SNI). To provide security, the SNI is limited to traffic from a single user; however,

traffic from multiple users is multiplexed over the backbone SMDS transport network. The SMDS interface protocol (SIP) defines how the subscriber communicates with a SMDS network across the SNI (BellSouth Telecommunications, 1994).

SMDS traffic management is based on the concept called sustained information rate (SIR). It is similar to the frame relay committed information rate (CIR). SIR makes use of access classes over a DS3 access circuit. An access class places a limit on the amount of sustained information that the customer premise equipment (CPE) can send across the SNI interface. The access class also places a limit on the burstiness of the information transfer over the SNI. The SMDS edge router keeps track of the traffic from each user through a credit manager. If credit is not available, the router will not service the user payload.

SMDS Internetworking

SMDS is implemented as a public packet-switched service. It provides a connectionless (datagram) service to the user. Each unit of data must contain complete end-to-end (user) addressing information and transmission delivery is not guaranteed. End-to-end connectivity over SMDS is accomplished through the use of an internetwork protocol such as IP (Figure 19) (Piscitello and Lawrence, 1991).

LANs can be bridged or routed across an SMDS subnetwork. In order to bridge LAN traffic over an SMDS subnetwork, address resolution must be carried out between the 48-bit LAN MAC address and the 60-bit SMDS E.164 address. The MAC frame from the local LAN destined for a remote location is encapsulated by the 802 subnetwork access protocol (SNAP). SNAP contains the 24-bit organizationally unique identifier (OUI) value

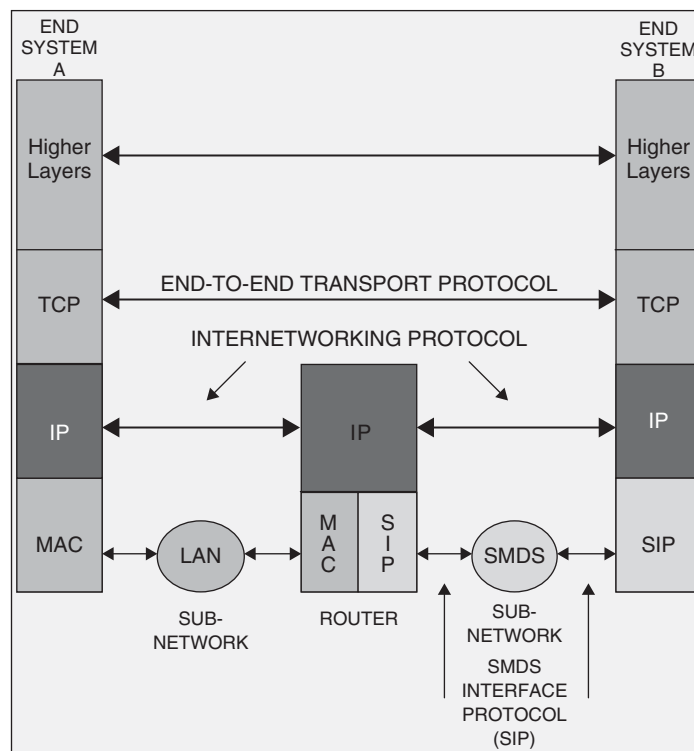

Figure 19: IP internetworking over an SMDS network

which identifies the organization and the 16-bit protocol ID (PID), which identifies the bridged MAC frame protocol. The SNAP protocol is then carried in a LLC frame. The resulting PDU is encapsulated in an 802.6 MAC frame (as an IMPDU). The IMPDU header contains the 60-bit E.164 SMDS address. Finally, the IMPDU is segmented into DMPDUs for transmission over the SMDS subnetwork to the remote bridge where the original MAC PDU is reconstructed and sent over the remote LAN.

DWDM Network

The two techniques that are used for multiplexing data over a communications channel are time division multiplexing (TDM) and frequency division multiplexing (FDM). TDM is a digital technique that divides a time interval into a number of time slots (Figure 20b). Each input data stream is assigned to one of the time slots. The bits from each time slot are interleaved and transmitted over the communications circuit as a single high-speed data stream at the aggregate speed of the individual data streams. Thus, the complete bandwidth of the communications circuit can be used to send the data. The reverse process is carried out at the receiver to recover the individual data streams.

FDM is an analog technique that partitions the bandwidth of a communications circuit into a group of subbands. Each input data stream is assigned to one of the subbands and is used to modulate the carrier frequency for that subband. The modulated signals from each subband are sent simultaneously over the communications circuit (see Figure 20a). Guard bands are used between the subbands to prevent the modulated signals on each subband from interfering with each other. At the receiver, the signals in each subband are separately demodulated to recover the original data streams.

Wave division multiplexing (WDM) is a technique for combining multiple individual optical subbands and

simultaneously transmitting these subbands over a single fiber. Thus, WDM is a form of FDM. Different colors (wavelengths of light) are used to transmit individual data streams over the optical fiber cable. Each color used consists of a narrow band of wavelengths. Each data stream is assigned to one of the colors (wavelengths) and the wavelengths are simultaneously transmitted over the optical fiber cable. Since the combined signal contains different wavelengths of light, the wavelengths can be separated at the receiver and the individual data streams can be recovered (see Figure 21).

Dense wave division multiplexing (DWDM) is just WDM that uses a very narrow channel spacing (1 nanometer [nm] or less). With DWDM a single fiber can multiplex together 80 or more separate wavelengths of light, where each of the wavelengths is being used to transmit a bit stream at a data rate of from 2.5 Gbps to 10 Gbps (Fujitsu Network Communications, Inc., 2002). The ITU-T has issued recommendation G.694.1 for DWDM that specifies the operation in the optical S, C, and L bands for high-quality, high-rate MAN and WAN services. It specifies frequency spacing of 100 GHz to 12.5 GHz (0.8 nm to 0.1 nm) centered on the 1550 nm wavelength.

A DWDM network consists of P-P links between nodes. The links consist of a variety of passive and/or active devices to combine, amplify, distribute, add, and drop the optical wavelengths (Figure 22). Passive devices are used to split and combine optical signals. Active devices include tunable optical filters, add/drop multiplexers, switches, and amplifiers.

Both P-P and ring topologies are used in DWDM networks. Protection in P-P systems is provided by redundancy. Parallel links connect redundant equipment at each end of the link. A ring configuration can have a hub station and one or more optical add drop multiplexer (OADM) nodes (Figure 23). Traffic originates and terminates at the hub node. At the ADM nodes selective wavelengths are dropped and added. Protection in DWDM ring networks can be implemented using USPR or BLSR techniques (Gumaste and Antony, 2002).

In the early 1990s, SONET/SDH rings became the primary means for providing bandwidth for metropolitan areas. The SONET/SDH multiplexing hierarchy was designed to be able to efficiently carry the digitized circuit switched voice traffic that was being sent over the telcos T1/E1 digital circuits. However, as the amount of data traffic being sent over MANs increased and the type of traffic changed from primarily circuit switched voice data to mostly IP-based packet data, SONET/SDH circuits no longer provided the optimum means for carrying the data. In addition, with the exponential growth in IP-based packet data there was a need for more and more bandwidth in the metropolitan area.

DWDM provides the means to address both of these problems. The use of DWDM enables an optical fiber cable to carry 80 (or more) times the amount of data than it could by using only a single wavelength. In addition, DWDM is capable of transparently carrying any type of traffic so that both packet data and circuit switched data can be carried efficiently (Fujitsu Network Communications, Inc., 2002; Gumaste and Antony, 2002).

Figure 23: DWDM ring network

Data Transport over DWDM

Because the SONET/SDH multiplexing hierarchy was not efficient for carrying packet data, many MAN service providers favored the use of the asynchronous transfer mode (ATM) protocol to carry packet switched data. ATM is able to encapsulate different protocols and traffic types into a common format for transmission over a SONET/SDH network. However, the use of ATM over SONET/SDH adds another level of complexity to MANs. In addition, the use of ATM incurs a significant overhead penalty from the cell and segmentation headers. Finally, the packet segmentation and reassembly required for ATM cell transmission limit the speed at which one can transmit packet data over the SONET/SDH MAN (Metz, 2000).

Packet over SONET/SDH (POS) provides a means for efficiently transmitting packet data over a SONET/SDH

network without the additional overhead, complexity and cost of ATM. However, POS still requires the use of SONET/SDH to transmit the packets over optical fiber links.

SONET/SDH can be done away with as a transport medium in DWDM MANs by directly transmitting the IP data over the optical transport. Because DWDM provides a large number of wavelengths, each wavelength can be used to carry a separate high-speed IP data stream. Thus there is no need for placing the IP data into an ATM or a SONET/SDH payload. However, existing IP over ATM over SONET/SDH and IP over SONET/SDH traffic can simultaneously be sent over the DWDM network by using separate wavelengths to carry these traffic types.

Multiprotocol Label Switching

The multiprotocol label switching (MPLS) protocol was developed to improve the performance of routing in an IP network by combining the datagram nature of IP with the label swapping hardware capability of switches. MPLS replaced the standard IP destination-based hop-by-hop forwarding paradigm with a label-swapping forwarding paradigm. Instead of using a longest match algorithm, label-swapping packet forwarding is based on a simple short-label exact match.

Routing protocol information is used to partition the entire forwarding space into forwarding equivalent classes (FECs). Each FEC is assigned a short, fixed-length, locally significant identifier known as a label. As packets enter a MPLS network, a conventional layer 3 lookup is performed and the next hop is determined. The label that is associated with the FEC is found and the packet is forwarded to the next hop with the assigned label.

Figure 24: MPLS label swapping

At subsequent nodes label switch routers (LSRs) use the label as an index into a table that specifies the new outgoing label and next hop. The label is swapped and the packet is forward to the next hop (Figure 24). This procedure eliminates the need for network-layer lookups in all but the first node. Information from the routing protocols is used to assign and distribute labels to MPLS peers.

The label distribution is done via a label distribution protocol (LDP). An MPLS node receives an outgoing label mapping from the peer that is the next hop for the data stream and allocates and distributes incoming labels to upstream peers for this data stream. The labels are used to construct a switched path through the network as each MPLS node splices the incoming label to the outgoing label (Metz, 2000).

Generalized Multiprotocol Label Switching

In order to be able to transport IP over a DWDM network it is necessary for the IP network to establish optical connections through the optical transport network. The MPLS working group proposed extensions to MPLS to control optical cross connects. The initial effort was called multiprotocol lambda switching (MP λ S). Further work on this capability was developed as part of the generalized multiprotocol label switching (GMPLS) standard (Gallagher, 2002).

The IP over DWDM model consists of IP routers attached to an optical core network. The optical core network comprises multiple optical cross-connects (OXC) that are interconnected by optical links. GMPLS applies MPLS control plane techniques to optical switches and IP routing algorithms in order to manage light paths in an optical network.

Extensions to the open shortest first (OPSF) and the intermediate system to intermediate system (IS-IS) routing protocols are used to advertise characteristics of the optical connection. Extensions to the reservation protocol (RSVP) and the constraint-based routed label distribution protocol (CR-LDP) signaling protocols are used along with a link management protocol (LMP) to set up and manage the path. RSVP and CR-LDP convey label requests along an explicit path. LMP manages control

channel availability, verifies connectivity of the component links and supports fault isolation.

Metro Ethernet

A Metro Ethernet network (MEN) is a network that uses high-speed Ethernet as the native transport protocol to provide connectivity services for broadband applications across a metropolitan area. A MEN connects geographically separate enterprise LANs within a metropolitan area and provides LAN users access to the public Internet. The MEN topology consists of point-to-point links that use Gigabit and 10-Gigabit Ethernet as the transport technology. The MEN nodes are either switches or routers. WAN links are used to connect MENs in different geographical areas (Metro Ethernet Forum, 2005a).

The fact that almost all data traffic on enterprise LANs uses Ethernet as the transport technology provides the rationale for a MEN. By extending Ethernet to the metropolitan area the data does not have to be converted to another format. This decreases the infrastructure costs because Ethernet equipment is much less expensive than the comparable frame relay or ATM equipment. In addition, bandwidth can be provisioned on demand from 1 Mbps to 1 Gbps.

The MEN is considered to be transport agnostic; it allows the use of other transport protocols to carry the Ethernet traffic such as SONET/SDH, WDM, or RPR. Thus, it is not necessary to replace existing infrastructure to implement a MEN. Instead it can be implemented over existing SONET/SDH and DWDM networks.

QoS

The major disadvantage for using Ethernet in the metropolitan area is that Ethernet has no built-in QoS capability. A requirement for a MAN is the ability to provide end-to-end QoS guarantees including connection admission, scheduling and policing, and prioritization of traffic. In addition there is a need for protection mechanisms that signal link failure and provide rapid reconfiguration of failed links as is done in a SONET/SDH network. In a standard Ethernet network recovery from link failure is done through the use of the spanning tree algorithm. However, it can take 10 or more seconds for reconfiguration

to take place as opposed to the 50 ms recovery time for a SONET/SDH network.

A number of mechanisms have been proposed to provide resiliency and fast recovery in a MEN. The IEEE 802.1s standard, multiple spanning trees, allows the Ethernet network to have more than one loop-free path in a virtual LAN (VLAN) environment. This provides redundant paths for greater reliability. The IEEE 802.1w standard, rapid reconfiguration spanning tree, implements a faster convergence algorithm that takes 1 second as opposed to 10 or more seconds. Finally, the IEEE 802.3ad standard, link aggregation, provides sub-second failover on trunk groups.

Service Types

The Metro Ethernet Forum specifies the use of an Ethernet virtual connection (EVC) to access a MEN (Metro Ethernet Forum, 2005b). The EVC is an association of two (or more) user network interfaces (UNI) where the UNI is a standard Ethernet interface between the customer equipment and the service provider's MEN. Two types of EVCs are specified, point-to-point and multipoint-to-multipoint. These correspond to two Ethernet service types, Ethernet Line (E-Line) and Ethernet LAN (E-LAN). The E-Line service is P-P. It can provide either a best effort full duplex connection with no performance assurances (analogous to a frame relay PVC) or it can provide QoS guarantees with a committed information rate (CIR), committed burst rate (CBR) and excess information rate (EIR) (analogous to a TDM private line service).

The E-Line service is implemented as either an Ethernet Private line (EPL) or an Ethernet Virtual Private Line (EVPL) (Figure 25). An EPL consists of a P-P Ethernet connection that uses reserved, dedicated bandwidth. From the Ethernet client perspective, the transport network looks like a wire. An EVPL allows the sharing of network resources among multiple customers to enable the efficient use of those resources. Only a single UNI is needed to support all of the EVCs.

The E-LAN service is multipoint-to-multipoint. It provides multipoint connectivity between two or more

UNIs. User data sent from one UNI can be received at one or more of the other UNIs. Like the E-Line service, the E-LAN service can provide either a best effort service with no performance guarantees or it can provide QoS guarantees.

As is the case of the E-Line service, the E-LAN service is implemented as either an Ethernet Private LAN (EPLAN) or an Ethernet Virtual Private LAN (EVPLAN). An EPLAN provides LAN-type connectivity between multiple customer sites through the use of dedicated channels. An EVPLAN can be considered to be a combination of an EVPL and a EPLAN. With an EVPLAN the transport channel bandwidth is shared among different customers.

ITU-T Study Groups 13 and 15 are working on developing standards for the Ethernet configurations documented in the Metro Ethernet Forum specifications. The Ethernet Service Framework is specified in ITU-T G.8011/Y.1307. The Ethernet Private Line Service and the Ethernet Virtual Private Line Service are specified in ITU-T G.8011.1/Y.1307.1 and ITU-T G.8011.2/Y.1307.2 respectively.

INDUSTRY FORUMS

In order to generate a market for new MAN products, companies that were instrumental in the development of new MAN standards and technologies have formed industry groups to promote the use of these technologies. The objective of these forums is to hasten the use of the technology by certifying products as conforming to the standards and carrying out interoperability testing of different vendors' products. Industry forums have been formed for both the WirelessMAN and the Ethernet MAN technologies.

WiMAX

The Worldwide Interoperability for Microwave Access (WiMAX) forum was formed in June of 2001 to promote the deployment of BWA through the use of a global standard (IEEE 802.16 and ETSI HIPERMAN) (WiMAX Forum,

Figure 25: EPL and EVPL services

2005; WiMAX Forum, 2006). To facilitate the adoption of WirelessMANs networks, WiMAX has implemented a process for certifying the interoperability of products and technologies. A key function of the WiMAX forum is the definition of a set of profiles. These profiles specify a group of parameters that are to be used to enable interoperability to be achieved between system components. The WiMAX forum has implemented product certification testing to ensure radio link and protocol conformance to the 802.16 2004 standard. In addition, it is carrying out interoperability testing to guarantee that different vendor products will work with one another. The WiMAX forum issues a WiMAX certification to organizations that meet its profile requirements and pass its certification testing process.

Metro Ethernet Forum

The Metro Ethernet Forum (MEF) was formed in May of 2001 by a group of local exchange carriers to promote the use of high speed Ethernet technology for metropolitan area networks (Metro Ethernet Forum, 2006). MEF now includes chip manufacturers and equipment vendors. The rationale for using Ethernet is that it is easier to administer and cheaper to maintain than SONET/SDH networks. To foster the acceptance of Ethernet MANs, MEF has specified a set of standards for implementing Ethernet MANs. The standards encompass protection, hard QoS, TDM support, service management, and scalability.

MEF has implemented a certification program for carrier-class Ethernet. MEF defines carrier-class Ethernet as an Ethernet environment that provides the same reliability and QoS as SONET/SDH. MEF has instituted a testing program to implement the certification process.

THE FUTURE OF MANs

A vast amount of optical fiber cable has been laid in metropolitan areas. These optical fiber cables provide the infrastructure for the high-speed MAN technologies that have been implemented to meet the growing need for bandwidth to carry the ever-increasing amount of data traffic being generated by business and residential customers. In the early 1990s, SONET/SDH rings were employed by the local telcos to provide a robust means to transport their circuit switched traffic. SONET/SDH enabled lower speed T1/E1 circuits to be multiplexed together so that the data could be efficiently carried over the SONET/SDH rings.

With the change in the mix of traffic from mostly circuit switched data to mostly packet switched data, SONET/SDH MANs that were designed to carry circuit switched traffic were not able to efficiently carry packet data traffic. Thus, new technologies were employed by the telcos to handle the growing amounts of packet data traffic. First the SMDS service, based on the IEEE 802.6 standard, was implemented to provide a transparent means to carry LAN traffic between customer sites in the metropolitan area. Next DWDM technology was introduced to meet the need for more and more bandwidth in the metropolitan area. By multiplexing 80 or more wavelengths on a single

optical fiber cable, DWDM enabled the existing fiber infrastructure to carry orders of magnitude more data.

Along with the use of new technologies, the development of new protocols allowed existing SONET/SDH MANs to better handle data traffic. Initially ATM was used to carry IP packet switched traffic over the SONET/SDH rings. However, ATM introduced its own inefficiencies, and IP/PPP over SONET/SDH was employed to reduce the overhead introduced by the use of ATM. Later IP/MPLS over DWDM was used to further reduce the overhead by allowing the SONET/SDH layer to be bypassed completely.

Changes were also made in SONET/SDH with the introduction of virtual concatenation and the use of the link capacity adjustment scheme. These changes enabled SONET/SDH to be able to carry packet data more efficiently. In addition, the GFP and the G.709 protocols were developed to transparently carry packet data over SONET/SDH rings and DWDM wavelengths.

With the development of the Gigabit and 10-Gigabit Ethernet standards, there has been a major effort to directly use Ethernet as a MAN technology. Because Ethernet is the dominant technology in the enterprise, it was natural to want to extend the use of Ethernet to the MAN environment. However, the benefit of using Ethernet as a MAN technology is somewhat mitigated by the fact that Ethernet does not provide a native QoS mechanism.

Recently two new MAN standards have been developed by the IEEE 802 committee to provide additional choices for implementing MANs. The 802.17 RPR standard provides a means to more efficiently use the dual ring fiber bandwidth by having both rings carry data. In addition, RPR supports a number of QoS mechanisms to provide customers with different classes of service for their data. The 802.16 WirelessMAN standard makes use of the 2–66 GHz portion of the RF spectrum to implement MANs using either P-MP or a mesh technology. The WirelessMAN technology enables a MAN to be implemented without the need to lay optical fiber cable.

Given the plethora of existing and new MAN technologies, it is clear that for the foreseeable future the marketplace will not converge on a single MAN technology. Unless it can be shown that cost savings can be realized by replacing existing SONET/SDH technology with new technology, the current SONET/SDH-based infrastructure will not be replaced in the near future. Thus, SONET/SDH optical fiber rings will continue to be used. However, the new protocols that have been developed will enable the existing SONET/SDH rings to more efficiently transport the ever-increasing amounts of IP packet data. Of course DWDM, RPR, and Metro Ethernet technologies are being used on new optical fiber infrastructure that is being added to handle the exponential growth in IP data.

As a result of the prevalence of Ethernet in the LAN environment, it appears that Metro Ethernet will gain significant market share as a MAN technology if its current limitations—a lack of QoS mechanisms and the inability to rapidly reconfigure when the network fails—can be overcome. Also, RPR should find at least a niche market given its ability to more efficiently use the optical fiber ring bandwidth and to provide the user with a range of service classes.

The most intriguing new MAN technology is the 802.16 WirelessMAN. It can be used to provide broadband infrastructure in developing nations where there is no existing infrastructure. However, that would not provide a major market for the technology. The other uses for this technology—to provide an alternative means of meeting the high-speed networking requirements of small business and residential customers and as a means of connecting WiFi hot spots and 3G cellular network to the Internet—is more interesting and more problematical. Whether there is a real need for such a capability and whether the 802.16 WirelessMAN can supply the needed bandwidth is still an open question. On the other hand, the 802.20 mobile wireless technology appears to be dead in the water. With the development of the mobile 802.16e standard and the problems being experienced by the 802.20 WG, it appears unlikely that there will be a market niche for 802.20. One thing is certain though. As new applications are developed that require additional bandwidth or new classes of service, there will be new MAN standards developed to meet those needs.

GLOSSARY

- ATM:** Asynchronous transfer mode is a cell-switching technology that provides QoS for the transfer of data and that is used to carry IP packet data over a SONET/SDH network.
- BLSR2:** A two-fiber bidirectional line switched ring that allows data to be sent over both of the fibers, but only uses half the bandwidth of each wire. In the event of a failure of the network the unused bandwidth can be used for backup.
- BLSR4:** A four-fiber bidirectional line switched ring that allows data to be sent over two of the fibers (clockwise on one and counterclockwise on the other). The other two fibers are used as a protect ring. In the event of a failure of the network the protect fibers are used for backup.
- Contiguous concatenation:** Combines the SPEs from lower speed SONET/SDH circuits into a single high-speed SPE. The payload of the higher speed frame is treated as a contiguous group of bytes.
- DQDB:** Distributed queue dual bus is a media access control technique for sending data over a dual fiber bus by constructing a single transmission queue for all stations attached to each bus.
- DWDM:** Dense wave division multiplexing is a form of frequency division multiplexing that uses different wavelengths on an optical fiber to transfer individual streams of data. DWDM uses closely spaced wavelengths so that an individual fiber can carry 80 or more separate data streams.
- G.709:** A ITU-T standard that uses a digital wrapper to carry packet data over an optical network. It uses an FEC technique to enable a longer span length and/or a higher bit rate for a SONET/SDH network or more wavelengths to be carried over a DWDM network.
- HIPERACCESS:** High performance radio access is an ETSI standard for a P-MP wireless access network that provides communications channels in the upper part of the millimeter portion of the RF spectrum (11 – 42 GHz).
- HIPERMAN:** High performance radio metropolitan area network is an ETSI standard for a P-MP wireless access network that uses the 2- to 11-GHz portion of the RF spectrum. It uses the OFDM modulation scheme to share the communications channel among the subscribers.
- IP over ATM:** A technique for encapsulating IP datagrams inside of ATM cell payloads in order to transfer the IP data over a SONET/SDH network. The IP datagrams are segmented to fit into the ATM payload and reassembled at the destination node.
- IP over SONET/SDH:** A technique for encapsulating IP datagrams directly inside of the SONET/SDH payload in order to transfer the IP data over a SONET/SDH network. The SONET/SDH payload uses contiguous concatenation to carry the IP datagram.
- Metro Ethernet Network:** A network that uses high-speed Ethernet (Gigabit/10 Gigabit Ethernet) as the native transport protocol to provide connectivity services for broadband applications across a metropolitan area.
- OFDM:** Orthogonal frequency division multiplexing is a form of frequency division multiplexing where a channel is divided into a large number of sub-channels and a portion of the data is sent over each of the sub-channels. With OFDM, the frequencies used for each sub-channel are selected to be orthogonal.
- RPR:** Resilient packet ring is a ring-based network that comprises a dual set of counter-rotating rings. RPR provides for efficient communications through the use of concurrent transmission, bandwidth reclamation, bandwidth reallocation and spatial and temporal bandwidth reuse. In addition, it provides for prioritization of the traffic through multiple classes of service and fairness through the use of a weighted fair access algorithm.
- SMDS:** Switched multimegabit data service is a service that is based on the IEEE 802.6 standard to provide a transparent means to carry LAN traffic between customer sites in a metropolitan area.
- SOFDMA:** Scalable orthogonal frequency division multiple access is a technique for sharing the OFDM bandwidth among the network subscribers by dynamically assigning a number of the sub-channels to each subscriber.
- UPSR:** Unidirectional path switched ring is composed of two counter-rotating rings: a working ring for data transfer and a protection ring for backup. In the event of a failure the data is switched to the protect ring.
- Virtual concatenation:** Uses multiple slower speed contiguously concatenated SONET/SDH channels so that the SONET/SDH payload matches the bit rate of the packet data.
- WiMAX:** The worldwide interoperability for microwave access (WiMAX) forum was formed in June of 2001 to promote the deployment of broadband wireless access systems in the 2–11 GHz portion of the RF spectrum through the use of the IEEE 802.16 and ETSI HiperMAN standards.

WirelessMAN™: The name given to the IEEE 802.16 standards that cover fixed broadband wireless access in the 2- to 11- and 10- to 66-GHz portion of the RF spectrum.

EVOLUTION OF NETWORKS

The computer network is usually defined as a set of autonomous computers interconnected (via different transmission media, e.g., twisted wires, coaxial cables, microwaves, satellite link, fiber optics, laser) together for exchange of information. It can also be defined as a model with associated protocols for different topologies, media access techniques, and signaling techniques that are required for communication between two remote nodes. The network finds its application in sharing of information processing resources (computers, printers, file servers) and bandwidth (frequency spectrum), distributed systems, exchange of multimedia information (video, images, audio, texts, graphics), accessing of remote information, and many other real-time applications. It has now become an integral part of organizations of any type like military, banking, air traffic, and other applications, which are solely dependent on the hardware (failure of which will collapse the whole system). The accessing of remote information includes: stock prices, airline schedules via public communication facilities, or dial-up for accessing our organization's databases. New applications like remote program, databases, and value-added communication facilities have been added economically. If we look at the evolution of data, we notice that in all these technologies, one of the main objectives was to define a high-speed with unlimited bandwidth network both for short and long distances that can transmit data, voice, video, and multimedia data.

CLASSES OF NETWORKS

There are mainly three classes of networks (based on the distance)—local area networks (LANs), metropolitan area networks (MANs), and wide area networks (WANs). LANs are primarily defined for short distance (few miles) applications within a single building typically using Ethernet technology, MANs are for a distance of a metropolitan area (about 50-100 miles) typically using optical fiber technology, whereas WANs or Internet cover a distance of thousands of miles within a country or between countries.

Local Area Network (LAN)

This is by far the most common type of data network that serves a local area (usually the area of a floor of a building, but in some cases spanning a distance of several miles). It finds its applications in industrial plants, office buildings, college or university campuses, or similar locations. In these locations, the LANs are owned by the organizations and as such we can install high-quality, high-speed communication links interconnecting nodes. Typical data transmission rates are 10 Mega (million) bits per second (Mbps) to 10 Giga (ten million) bits per second (Gbps) for resource sharing among the users within the organization.

Realizing the continuous trend of introducing LANs by different organizations for their applications, it was felt that these LANs have to be standardized by appropriate International Standards Organization (ISO) and as such IEEE 802 committee (grouper.ieee.org, 2006; standards.ieee.org, 2006) was formed to define standard LANs as 802.3 (Ethernet), 802.4 (token bus), 802.5 (token ring), and 802.11 (wireless). In order to avoid any technical and integration problems, ISO defined a uniform architecture known as Open System Interconnection (OSI) reference model standard that provides interoperability among these LANs. The IEEE 802 LAN model further partitioned the data-link layer into two sub-layers as logical link control (LLC) and media access control (MAC) (Figure 1).

The most widely used LAN is the Ethernet LAN developed by the Xerox Corporation. The first Ethernet LAN offered data rates of 10 Mbps Base-T and were extended to offer data rates of 100 Mbps, 1 Gbps. The Ethernet uses frame size of maximum 1500 bytes and in fact has been used in 10/100/1000-Mbps Ethernet devices. The Internet protocol version 4.0 (IPv4; currently being used) supports maximum size of 64 Kbytes, whereas Internet protocol version/new generation (IPv6 or IPng; currently being considered for the future) will support a packet of size of up to 4 Gbytes. The current 10-Gbps Ethernet (10GBASE-T) is being used efficiently on backbone connection end-to-end between networks. It uses the popular IEEE 802.3

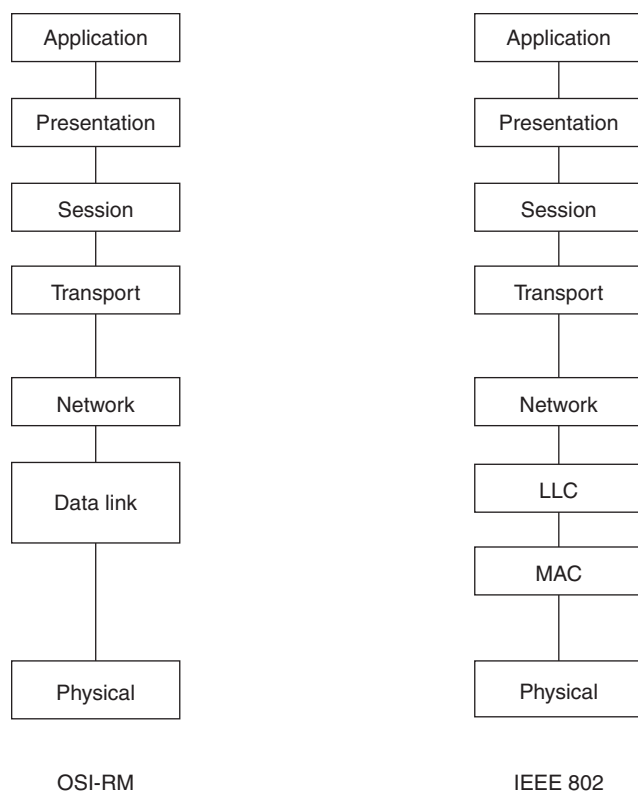

Figure 1: Comparison of OSI-RM and IEEE 802 model

Ethernet MAC protocol, its frame format, and size. Like Fast Ethernet and GB Ethernet, it also works on full-duplex transmission and covers a distance of 300 meters (m) (multimode fiber) and 40 kilometers (km) (single-mode fiber). It can replace existing networks that are using ATM and SONET multiplexers on OC-48 ring with a simpler network of 10-GB Ethernet switches for a data rates of 2.5 Mbps to 10 Gbps. It can also be used to interconnect LANs, MANs, and WANs. It is based on Ethernet media access control, its frame format, and size.

10-GB Ethernet has taken over fiber GB Ethernet, which offers data rates ten times greater than 10-GB Ethernet (IEEE). Meanwhile copper 10-GB Ethernet is expected to replace the twisted pair soon and in fact there are many commercially available adapters that provide connectivity between them. Ethernet over copper covers a distance of 15 meters. The GB Ethernet data-link layer encapsulates packets with a frame header (that included MAC addresses and other header control information) and 32-bit frame check sequence (FCS) before encoding to send across fiber or copper media. It supports optical fiber, twisted pair cable, and balanced copper cable (physical layer standards). IEEE 802.3z (grouper.ieee.org, 2006; standards.ieee.org, 2006) introduced the following standards: 1000BASE-SX transmission over multimode fiber (maximum distance of 220 meters, useful in large office buildings and carrier central internet exchanges), 1000BASE-LX over single mode fiber (2km to 20km), 1000BASE-CX for transmission over balanced copper (maximum distance of 25km per segment, now obsolete), 1000BASE-T (also known as IEEE 802.3ab) standard over copper (maximum distance

of 100/150km). 1000 BASE-TX was created and proposed by the Telecommunication Industry Association and requires two pairs (commercial failure). These standards use 8B/10B encoding and support a data rates of 1000 Mbps to 1250 Mbps.

There are non-IEEE 802 LANs (proprietary) that can also be used for resource sharing. Interconnecting devices (i.e., repeaters, bridges, and switches) allow LANs to be connected together to form larger LANs. A LAN may also be connected to another LAN or to WANs and MANs using a router. A brief discussion on interconnecting devices is given below.

Internetworking Devices

The following section describes the functions of each of these interconnecting devices.

Repeater. It is used at the physical layer of OSI-RM that regenerates incoming electrical, wireless, or optical signals. The quality of data signals degrade or fade out after a limited distance in physical media like Ethernet or Wireless Fidelity (Wi-Fi) transmission used in wireless communication and repeater attempts to preserve signal integrity and extend the distance over which data can safely travel. Wi-Fi was primarily being used in place of 2.4GHz 802.11b standard where the access point is being used as repeater only when it is operating in repeater mode. Now it refers to any type of 802.11 specifications (whether 802.11b, 802.11a, or dual-band) for interoperability as advocated by Wi-Fi Alliance as Wi-Fi Certified that works with any brand of access point with any other brand of client hardware. It was intended to be used for mobile computing devices like laptops and LANs, but now is being used in applications like Internet, VoIP phone access, gaming, TVs, DVD players, Intelligent Transportation Systems, and mobile commerce IEEE 802.11p (grouper.ieee.org, 2006; standards.ieee.org, 2006). It supports connectivity in peer-to-peer mode that enables devices to connect directly with each other.

Hub. A special type of network element that finds its applications in home and small business is known as a hub. A hub is a small rectangular box, often made of plastic that receives its power from an ordinary wall outlet. A hub joins multiple computers (or other network devices) together to form a single network segment. On this network segment, all computers can communicate directly with each other. Ethernet hubs are by far the most common type, but hubs for other types of networks such as USB also exist. This works at the physical layer of OSI-RM and cannot read any of the data passing through it and also is not aware of source or destination. Generally speaking, a hub receives incoming packets, amplifies the electrical signal, and broadcasts these packets out to all devices on the network including the one that originally sent the packet. There are three types of hubs: passive, active, and intelligent. Passive hubs (concentrator) do not amplify the electrical signal before broadcasting over the network. Active hubs (multiport repeater) amplify the signal (similar to repeater). Intelligent hubs add extra features to an active hub and are typically stackable (built in such

a way that multiple units can be placed one on top of the other to conserve space). They include remote management capabilities via SNMP and Virtual LAN. A good five-port Ethernet hub can be purchased for less than 30 dollars, whereas a USB hub costs only a bit more.

Bridge. It is used for connecting and packet forwarding between identical networks (homogeneous networks) and operates at the data-link layer. Bridges are generally used to segment a LAN into a couple of smaller segments and have only a few ports for LAN connectivity. It is based on store-and-forward switching concept and does not provide any dedicated bandwidth to each segment. It forwards the frames between links. New bridges have been defined and standardized that can be used to interconnect different types of networks (heterogeneous).

MAC-layer bridge connects two Ethernets (IEEE 802.3) or token ring LANs (IEEE 802.5), whereas different types of LANs, such as Ethernet and token ring, can be connected by bridge (working at the data-link layer) as shown in Figure 2. Any frame coming out from Ethernet LAN host will be subjected to the same MAC sub-layer at bridge node. The mapping between frames of Ethernet and token LAN is performed by LLC sub-layer at bridge. The frame from bridge will have same frame format as that token ring host and as such will be interpreted as its frame. In the same way, the frame format mapping is done by LLC at bridge for frame coming out from token ring host to Ethernet host.

Switch. Switching technology is becoming an alternative to bridge-based interconnecting implementation as it offers better throughput performance, higher port density, lower cost for ports, and greater flexibility in configuration capability. It may soon replace the bridge-based interconnection and routing technologies. It is generally used to segment a large LAN into many smaller segments and have many ports. Small switches such as Cisco Catalyst 2924XL have 24 ports that can create 24 different network segments. Larger switches, such as Cisco Catalyst 6500, have hundreds of ports. LAN switch is used to interconnect multiple LAN segments. It provides dedicated, collision-free communication between network devices, with support for multiple simultaneous conversations.

LAN switches are designed to switch data frames at high speeds.

Gateway. Heterogeneous networks are defined as a collection of different types of networks that have different protocols (from different vendors) at data-link and network layers. These networks (private or public) can communicate with each other through gateway, which operates at the network layer of OSI-RM. It maintains a routing table to provide internetworking addresses and offers compatibility between protocols of all three lower layers (physical, data, and network). It is also known as a router. Many gateways will require operation through all seven layers of OSI-RM. Examples would be the IBM LAN with bisynch and EBDIC connected to another type of LAN, such as Ethernet. 802.11a and 802.11b are standards. 802.11g standard offers wireless interface while 802.11n (emerging standard) is a transition at a frequency of 2.4GHz or 5GHz with data rates of 600MHz. 802.11b and 802.11g are compatible and devices can coexist in the same network.

Fiber Distributed Data Interface (FDDI)

It is 100-Mbps LAN, which uses optical fiber as a transmission medium and is mainly based on packet-switching approach for data communication. The FDDI protocol is based on token ring media access technique and uses ring topology that does not impose any restrictions on the number of stations and the length of links. The ring topology offers point-to-point communication and is being used by MANs as well. It offers features like reliability, availability serviceability, and maintainability even in the presence of broken link or failed node. The FDDI is being used as a backbone LAN in many corporations and universities.

The performance of ring topology can be improved by using two rings such that in case of a failed link or node, it can be reconfigured to bypass it and still offer same response without affecting the topology or the nodes. This finds its application in the implementation of MAN (IEEE 802.6) (grouper.ieee.org, 2006). The layers of FDDI node conform to both IEEE 802 and OSI-RM.

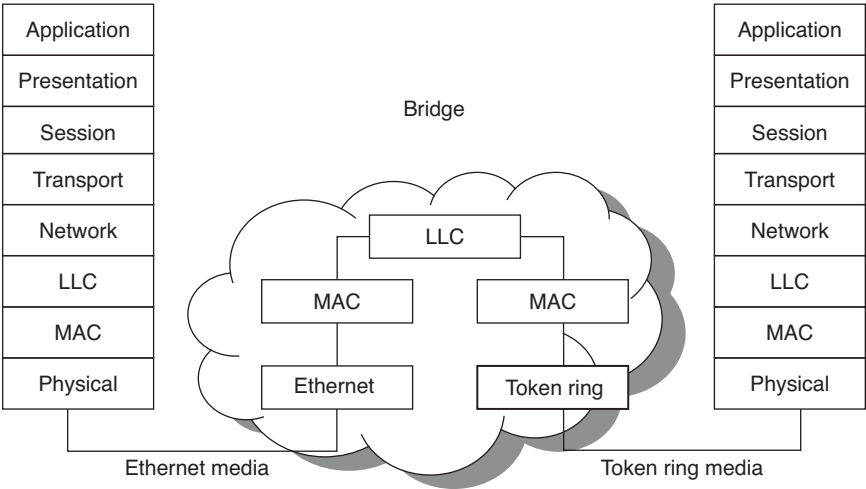

Figure 2: Bridge connectivity between different types of LANs

Fiber Distributed Data Interface-II (FDDI-II)

An enhanced version of FDDI known as FDDI-II was introduced that offers integrated services of packet switching and isochronous (requiring timing coordination for voice and digital video transmission) services at a bandwidth of 100 Mbps. It supports both packet switching and circuit switching for data transfer and as such the entire bandwidth can be allocated to both packet-switched circuit-switched data networks. The FDDI-II ring supports high-performance processors, high-performance workstations, mass storage system, distributed data base systems, and a switchable backbone LANs for a number of functions.

If FDDI-II ring network is working in a packet-switched mode, it may well be used as a backbone for interconnection devices (like gateways) to public data network. With packet-switched service, FDDI packets are of variable length and contain various control symbols, addresses, delimiters, for identifying the fields within packets.

If FDDI-II is working in circuit-switching mode, no addressing is required. Instead it establishes a connection upon request and requires the knowledge of time-slot and prior mutual agreement with the destination user node. In FDDI II, the synchronous operation typically works on packet-switching but can also operate on circuit-emulation (used in ATM networks). This emulation accepts all continuous bit rate information (generated by continuous bit rate [CBR]). The switching and multiplexing operations are always performed by higher layers (data-link layers network layers, and above layers), whereas transmission functions are performed by lower layer (physical).

FDDI-II handles three types of packets or traffic: 1) asynchronous: packets of different lengths arriving randomly, 2) synchronous: packets arrive at regular interval with pre-defined number and size defined, and 3) isochronous: packets are well defined in size, their arrival during time slots, the use of entire bandwidth, and other features and are well known in advance. An isochronous service is offered by wide band channel (WBC), which describes circuit-switched connections. A total bandwidth of 98.304 Mbps is available for a variety of applications. The isochronous bandwidth (WBC) may be allocated to different sub-channels supporting different virtual circuit services like (video, voice, image, control data, real-time data) within bandwidth of a WBC or more WBCs. The maximum length of a ring is about 200km and supports up to 1000 users. The maximum distance between two nodes is 2 km.

Wireless Network Technology

Wireless networking technology offers wireless connection services across short distances for global voice and data communication. It uses infrared light, radio frequency and carrier currents media for wireless communication services via unlicensed frequencies of 10 Mbps. A variety of devices used for wireless networking include desktop computers, laptop computers, hand-held computers, personal digital assistants (PDAs), cellular phones, pagers, pen-based computers, and mobile computing. To lower the costs, ensure interoperability, and promote widespread adoption of wireless LANs, Electrical and Electronics Engineers (IEEE) working group 802.15 (standards.ieee.org, 2006), Internet Engineering

Task Force (IETF), Wi-Fi Alliance: WFA (formerly known as Wireless Ethernet Compatibility Alliance: [WECA]) and International Telecommunication Union (ITU) are working on several standardization processes. Wireless networks can also be classified as wireless LANs, wireless MANs, and wireless WANs (Hura and Shinghal, 2001; grouper.ieee.org, 2006; standards.ieee.org, 2006).

Wireless technology has revolutionized a number of applications and market segments and encompasses a number of standards including:

- Wi-Fi (802.11 a/b/g/n)
- WiMAX (802.16)
- Ultra Wide Band (UWB)
- Bluetooth
- ZigBee (802.15)
- Near Field Communications (NFC)
- Mesh
- 3G+

Out of these wireless technologies, Wi-Fi (802.11) has become more popular in laptops, communities, and cities. It poses some constraints in terms of performance flexibility, power consumption, and ease of use. In 1999, several industries formed a global, non-profit organization for adopting a single worldwide accepted standard for high-speed wireless local area networking (Wi-Fi Alliance). This alliance has over 3000 interoperable certified products.

Wireless Local Area Network (WLAN)

Wireless LANs can be used within corporations, buildings, and public areas such as an airport and as a temporary or supplement service for the users within building. Wireless LANs with a connection to Internet or any other similar network via digital subscriber line (DSL) is known as wireless DSL. It typically can be configured in two ways. It can define infrastructure where wireless nodes (radio network card or modem) are connected to wireless access point that provides bridge between nodes and existing network backbone. Alternatively, it can allow users within a conference room to form a temporary ad hoc network without any access points. IEEE approved 802.11 standards for wireless LAN (also known as wireless Ethernet or Wi-Fi) were previously known as Wireless Ethernet Compatibility Alliance and now known as Wi-Fi Alliance and offer a data rate of 1 to 2 Mbps.

Other ratified IEEE WLAN standards IEEE 802.b (11 Mbps over 2.4 Gigahertz frequency band within 50 to 100 meters), 802.11a (54 Mbps over 5-GHz frequency band), and 802.11g (54 Mbps over 2.44-GHz). WLAN link speed drops with a distance reaching out about 100 meters in open space. 802.11 offers quality of service (QoS) support for LAN applications (network card can be used in a new QoS Basic Service Set: QBSS) such as voice over wireless IP (VoWIP), high-speed Internet access with full motion video, high fidelity, audio and voice over IP, mobiles, and users of PDA and other bandwidth and delay-sensitive applications. It supports seamless interoperability between business, home, and public services like airports and hotels with multimedia capability.

It provides classes of services with managed levels of QoS for data, voice, and video. It supports two types of modes for managing different categories of traffic: enhanced distribution coordination function (EDCF) (based on carrier sense multiple access with collision avoidance) and hybrid coordination function (HCF). EDCF seems to be gaining more acceptance than HCF. It operates at radio frequencies between 2.400 and 2.4835 GHz (802.11b) or 5.725 to 5.850 GHz (802.11a). Enterprise WLAN is currently being deployed in small-scale applications like retail and health care systems and is slowly becoming popular for large-scale applications. A new evolving architecture is supposed to shift some key functions from AP to centralized WLAN switch/appliance is helping these large-scale applications by easing security and management concerns.

The following is a brief discussion on various 802.11 specifications (grouper.ieee.org, 2006; standards.ieee.org, 2006)

802.11—original WLAN standard, supports 1 Mbps to 2 Mbps in 2.4-GHz band using either frequency hopping spread spectrum (FHSS) or direct sequence spread spectrum (DSSS)

802.11a—extension of 802.11a, high-speed WLAN standard (5 GHz), supports 54 Mbps, uses orthogonal frequency division multiplexing encoding rather than FHSS or DSSS

802.11b—also known as 802.11 high rate or Wi-Fi, WLAN standard for 2.4 GHz, supports 11 Mbps (with a fallback to 5.5, 2 and 1 Mbps), uses only DSSS

802.11d—automatically configures devices to match local RF requirements, international roaming

802.11e—quality of service (QoS) specifications for all IEEE WLAN radio interfaces

802.11g—uses additional modulation for 2.4 GHz band and supports data rate of 54 Mbps

802.11h—explains the spectrum management of 5 GHz band

802.11i—approved standard that provides security for both authentication and encryption protocols, it encompasses 802.1X, temporal key integrity protocol (TKIP), advanced encryption standard (AES) protocol becomes the Wi-Fi WLAN technologies. AES is stronger than Wi-Fi protected access (WPA) mechanism

802.11n—supports higher throughput improvements, offers data rate of 500 Mbps.

Virtual LAN. This is another category of LAN where the connected devices do not have to be physically connected to the same segment (while these are needed in hubs, bridges or switches). It operates at the data-link layer of OSI-RM. It can also be configured to map directly to an IP network or subnet that may involve the network layer as well. The VLAN technology is based on broadcasting messages to all connected devices (end nodes) within VLAN without the need for a router and uses the management software that detects the port on a switch or any station without changing MAC or IP address. The 802.1Q specification supports the VLAM membership to be inserted into Ethernet frames with ability of setting

profiles for each port by a central switch. The membership can be implemented in three different ways as port-based, MAC-based, and protocol-based. LAN emulation (LANE) software over ATM offers full support on existing LAN-based applications without any changes in backbone services.

Wireless Metropolitan Area Network (WMAN)

It provides users to establish connections between multiple locations within metropolitan area and can be used as a backup for wired networks. The data communication is based on either infrared wave or radio wave technologies. It offers high-speed access to Internet via broadband wireless access networks and uses either multichannel multipoint distribution service (MMDS) or local multipoint distribution service (LMDS). IEEE 802.16 (8,11) Working Group for broadband wireless access standards is still developing its specifications. It supports both fixed and mobile broadband wireless access and is concentrating on standardization of fixed BWA systems focusing on licensed spectrum near 30 GHz, but is intended to be broadly applicable from 10 to 66 GHz. A group World Inter-Operability for Microwave Access (WiMAX) supports 802.16a that provides broadband services at a rate of 4000 Mbps over a distance of 50 km. 802.20 (below licensed band of 3.5 GHz) and IEEE 802.16e (in licensed band of 2 to 6 GHz) specify standards for mobile air interface for wireless broadband access (BWA) at data rate of 1 Mbps Internet services to mobile users up to 15 km or more. Carrier currents LAN use power lines for transport.

The industry trade group WiMAX Forum (<http://www.winmaxforum.org>) has defined WiMAX as a broadband wireless access alternative to cable modem service, telephone company, digital subscriber line (DSL), or T1/E1 service. It is an IEEE standard 802.16-2004 (fixed wireless applications and 802.16e-2005 (mobile wireless) (<http://ieee.org>). It has the potential to replace a number of existing telecommunication infrastructures. The fixed wireless standard can be used for telephone company's copper wire networks, cable TV's coaxial cable infrastructure while offering Internet service provider (ISP) services. The mobile wireless standard can be used for cellular networks. Many times we may get confused between Wi-Fi and WiMAX technologies. Wi-Fi technology provides limited security, QoS, and a throughput of 11 Mbps within a distance of 100 yards in one floor of the building or a home. WiMAX on other hand provides multilevel encryption, dynamic bandwidth allocation for voice and video and a throughput of 72 Mbps within a distance of six miles for a city with one base station. For data rates of different wireless architecture, visit <http://www.bcr.com/architecture>.

Wireless Wide Area Network (WWAN)

Wireless technology for WANs allows users to establish wireless connections with public or private networks. Wireless service providers use multiple antennas or satellite systems. The second-generation technology (limited roaming capability) uses global system for mobile communication (GSM), cellular digital packet data (CDPD), and code division multiple access (CDMA). The

global standard for third-generation technology (global standard for global roaming capability) is under consideration by ITU.

Wireless Personal Area Network (WPANs)

This new class of wireless technology finds its use in establishing ad hoc wireless communication within PDAs, cellular phones, PCs, wireless printers, storage devices, pagers, or laptops within a distance of up to 10 m. Bluetooth and infrared technologies are being considered for this application by providing short-range wireless communications and simplified communication and synchronization. Both technologies eliminate wires and cables, and facilitate data and voice communication and possibility of ad hoc networks. Bluetooth uses radio waves for transmitting the data over a distance of 30 feet and in fact can go through walls and pockets. It uses a fast acknowledgement and frequency hopping scheme to make the link robust in noisy environment. It is based on globally available frequency band of 2.4GHz and provides compatibility to PCs, Apple computers, Palm OS-based handheld devices, mobile phones, and other peripherals within 30-foot range wirelessly. Infrared connection can be established for a small distance of one m or less. Bluetooth version 1.1 was ratified as IEEE 802.15 (standards.ieee.org, 2006) a long time ago. Bluetooth version 2.0 was completed in 2004 to increase link speed from 780 Kbps to 3 Mbps. Neither Bluetooth version is interoperable with 802.11 (i.e., Bluetooth devices cannot communicate with an 802.11 device). However, standard Bluetooth co-existence techniques have been defined, because Bluetooth and 802.11b/g use the same 2.4-GHz frequency band and thus would otherwise (and often do) generate radio interference. This technology is less complex, offers low power consumption, supports interoperability, and coexistence with 802.11 networks (For details read standards.ieee.org, 2006).

Wireless Local Loops (WLLs)

This new technology offers fixed wireless access (in addition to phone service) at several MHz of bandwidth for high-speed Internet access and data transfer and seems to be better than mobile access provided by cellular and PCS. It has become very popular among the users of local phone loops over fixed cellular networks.

Personal Communication Service (PCS)

PCS is similar to cellular, operates in 1900-MHz band and is based on three technologies in North America as GSM 1900, CDMA IS-95, and TDMA IS-136. Code division multiple access (CDMA) uses the same assigned frequency for transmitting a very wide signal as many other stations and does not offer any coordination between stations. Time division multiple access (TDMA) divides the frequency pair into several time slots and provides the frequency during that assigned time slot. Frequency division multiple access (FDMA) allocates its own specific radio frequency pair for entire duration of call. Local multipoint distribution systems (LMDS) is defined for fixed wireless access that can offer very high bandwidth and is based on line of sight. LMDS technology offers point-to-point and multipoint applications (e.g., high-speed Internet access,

telephony, cable TV programming transmission) within a band of 28 to 31 GHz and is based on spread spectrum to support very high bit rates for two-way data transfer. IEEE 802.15 Working Group (standards.ieee.org, 2006) is developing standards for physical and MAC layer specifications for short distance (up to 10m in all directions) wireless connectivity with fixed, portable, and moving devices within personal operating space (POS).

Mesh Network

A mesh network can be defined as a network that provides direct links to each other between all the nodes of the network. It works well when the nodes are located at scattered points that do not lie near a common line. The underlying topology can be either full mesh (all nodes are directly connected to each other) or partial mesh (some nodes are connected to all the other nodes and other nodes are connected to those nodes for exchange of data). If one node can no longer operate, all the rest can still communicate with each other, directly or through one or more intermediate nodes. Figure 3 shows full mesh topology. The connections can be wired or wireless. It is reliable and offers redundancy but is very expensive (as a result of a large number of connections).

Wireless mesh networks can offer a variety of applications and solutions securely and cost-effectively for both enterprises and end users. These networks are highly scalable and cost-effective and offer end users seamless broadband wireless access beyond traditional wireless boundaries and provide easy deployment in the areas that do not or can not support wired backhaul. Some of the applications of meshed wireless network include city governments and municipalities (residential areas, parks), which may benefit from enhanced employee safety, efficiency and improved business, campus environments (enterprise, universities), shopping centers, airports, manufacturing, military operations like disaster recovery, and public safety. The existing infrastructure such as installation of extensive Ethernet cabling in leased facilities can be used for wireless mesh networks to provide new opportunities for generating revenue, enhanced business productivity, and convenient services. The wireless mesh network can be used for both indoor and outdoor and will find its use where Ethernet cabling is prohibitive to install or leased backhaul needs to be minimized. This network is finding its use in all the WANs and mobile computing.

Metropolitan Area Network (MAN)

A metropolitan area network (MAN) is the second type of network that finds its applications in metropolitan area

Figure 3: Topology of mesh network

(over 10 miles and less than 100 miles). It is a relatively new class of network and offers services through network service carrier in the same way as services offered by Internet service provider (ISP). It often uses fiber optic as transmission media for data communication. It is generally not owned by a single organization, but instead is owned by either consortium of users or by network providers (standards.ieee.org, 2006). IEEE 802.6 (standards.ieee.org, 2006) standard based on distributed queue dual bus (DQDB) has been defined. Figure 4 shows a typical MAN architecture that can be used to provide resource sharing (LAN) and shared access to WAN.

LANs provide resource sharing and groups of users, whereas MANs allow the users to share social, educational, and career challenges who are dispersed at large distance (over 10 miles, but less than WANs range). It can

reach rural areas where the government agencies across a city or county can create a community network, but needs a substantial budget to lease or install fiber across the county and also digging of trenches. This problem can be alleviated by installing wireless communication over MAN that will provide point-to-point and point-to-multipoint links with higher bandwidth. Wireless MANs will be a lot cheaper in terms of expensive fiber infrastructures and leasing of lines from carrier companies.

Wide Area Network (WAN)

A WAN is a data communications network that covers thousands of miles and often uses transmission facilities provided by telephone carriers. Invariably, all WAN technologies focus on the lower three layers of the OSI-RM. Figure 5 shows the relationship between OSI-RM and

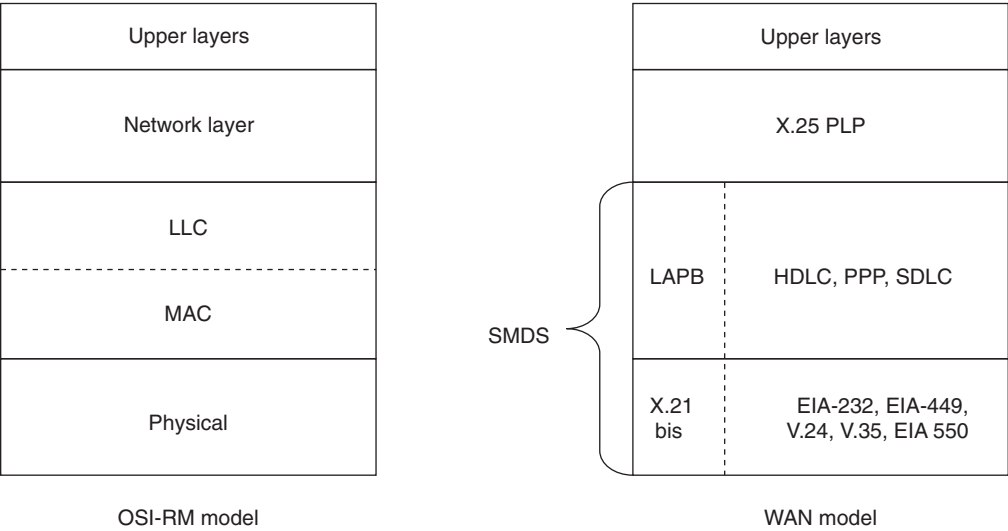

Figure 4: Typical MAN architecture

EIA: Electronic Industries Association
SMDS: Switched Multimegabit Data Service

Figure 5: Relationship between OSI-RM and WAN model

WAN model of different technologies. The WAN protocols operate in these lower layers of the OSI model.

Point-to-point communication is being provided by a single, pre-established WAN logical circuits/links from the customer premises through a carrier network and is usually leased from a carrier as leased links. These circuits are generally priced based on bandwidth required and distance between the two connected points. In a packet-switching setup, networks have connections into the carrier's network, and many customers share the carrier's network. The carrier creates virtual circuits between customers' sites for the exchange of packets through the network.

NETWORK SWITCHING TECHNIQUES

The speed and capacity of any networks are highly influenced by the switching method used. A switch in networking can be considered the heart of the data communication (similar to engine in a car). Appropriate switches have to be used when a network (be it public or private) based on that switching technique (circuit or packet) is selected, although, we can get plug-in switches that can be used interchangeably on the networks. When the switches are used with different types of networks, different interfaces have to be provided by the switching equipment. The following section describes in brief the main features of these switching techniques.

Circuit Switching

In this technique, a circuit or link connection is established between source and destination users/nodes for the entire duration of the connection before sending any data and it supports end-to-end connection between the users. During the established connection, the entire bandwidth is allotted to the users/nodes. An unused bandwidth and resources by the user/node will be wasted and can not be used by other users/nodes or even by the network. It offers minimum delay and guarantees the delivery of the packets in order between nodes. The circuit switching supports different types of multiplexing techniques (space, time). For each of the circuits that are multiplexed, the same time slot with the frame is used during the entire duration of the connection. Similarly, a table describing the relationship between incoming and outgoing links along with time slots at each of the switching nodes is maintained. The time slots are fixed for both sides of switching for the duration of the connection. An initial set-up time in some applications may become a serious problem, for example, voice and video communications. It finds its use in N-ISDN for offering a fixed data rate and capacity network connection and is not suitable for bursty (irregular) traffic applications.

Fast Circuit Switching

This technique is a modified version of circuit switching in which the resources are allocated during the transmission of data and are released immediately after the transmission is completed. It is a form of connectionless packet switching in the sense that during the set-up of the connection time, a request for destination bandwidth for

the connection is stored inside the switching system and allocates header for this data. The resources are allocated immediately after the source starts sending the information. One of the major drawbacks with this technique is its inability to allocate enough resources to unexpected bursty traffic.

Packet Switching

In this method, a fixed/variable size of packet (defined by the network) is transmitted over the network. Each intermediate node transmits packets to next node based on the availability of routes. An established logical link offers the entire bandwidth to the packets during its transmission. After the packets have been transmitted to the next node, the entire bandwidth of the link is released for other packets. In some packet-switched networks, all the packets are stored in main memory to reduce the accessing time of the packets, whereas other networks use other memory devices. As a result of this, the throughput offered by networks based on this switching can be improved.

Packet-switched networks allow the end nodes/users to share the media and its bandwidth. There are two methods of packet switching that have been used in networks. The first method is based on a variable length packet where packets initiated from the source switch between segments of networks before reaching destination. It is usually used in efficient and variable data rate applications. The second method is based on statistical multiplexing where the bandwidth of media is used efficiently by grouping the packets together into one big packet.

Fast Packet Switching

The fast packet switch is based on the concept of T1 multiplexer, which executes the protocol at the physical layer only. The conventional T1 multiplexing carrier system generates 24 channels of 64Kbps and uses time division multiplexing (TDM) technique. This technique suffers from wastage of bandwidth to other channels, and is not suitable for applications like bursty traffic or applications with variable and high data rates that require larger bandwidth.

WIDE AREA NETWORKS

Both types of networks (circuit- or packet-switched) are based on the concept of switching that is the backbone for any technologies for a high-speed WAN. The following is a brief description of each of these technologies for WANs.

Integrated Service Digital Network (ISDN)

This is a single digital network that transmits integrated voice and data information over the same transmission media. In most of the countries, the existing public switched telephone networks are being converted or replaced for full digital operations. It offers two types of interfaces (basic rate interface (popular in the United States) and primary rate interface (popular in Europe) and implements two types of networks (voice and data) within ISDN implementation. It offers two channels: bearer (B) and delta (D). The B channel has a bandwidth of 64Kbps and can be configured either for circuit switching or packet

switching connection. The D channel on the other hand is for signaling purposes and operates in packet-switched mode at a speed of 16 Kbps.

BRI offers 2B + D service at the rate of 144Kbps (2X64Kbps + 16Kbps), whereas PRI offers 23B + D service at the rate of 1.544Mbps (23X64 + 64) (U.S.) and 30B + D service at the rate of 2.56Mbps (23X64 + 64) (Europe).

Applications of ISDN: One of the earlier popular applications of ISDN has been videoconferencing and, in fact, became a standard service of ISDN. Recent years has seen a shift in ISDN services where it may not even include video conferencing as other technologies seem to be more appropriate for this application. In this service, the presentations, or seminars can be transmitted over TV screens anywhere around the globe if ISDN connection between them is available over T1/T3 or any other link. It offers two-way communications for both point-to-point and multipoint configurations between the users. Different conference places can be connected to receive point-to-point services and or multipoint (where small number of users can communicate with each other and discuss common documents, display the user's live pictures either one at a time or all of them together on the screen) services. All these options are usually handled by video service providers.

As a result of bandwidth limitations of ISDNs and basic rate interface of (2B + D) only, the TV signals (typically of 6 MHz bandwidth) cannot be transmitted over it. For transmitting uncompressed TV signals, a separate TV network may be required as ISDN supports only compressed TV signal. As a result of lower bandwidth, this network is also known as narrowband-ISDN (N-ISDN).

Broadband-ISDN (B-ISDN)

In order to extend the concept of ISDN's integration of voice and data into other types of services like video, multimedia, and images, a new unified network termed broadband-ISDN (B-ISDN) offering these services was introduced in the mid-80s. It is a service-independent network that transports these services by requiring transmission channels of supporting more data rates than PRI (1.544 Mbps) defined by N-ISDN and allows the users to share the resources of various networks for different services.

Optical transmission (based on fiber optics) is the main force for B-ISDN as it offers very high bandwidth and data rates over a longer distance. The diameter of fiber is very small and it offers low weight and volume. It is immune to electromagnetic fields and as such offers low transmission error probability. There is no cross talk between fibers and is very difficult to tap and offers virtually an unlimited bandwidth. The basic B-ISDN interface across broadband user-network interface offers 155 Mbps, whereas a second B-ISDN interface offers 622 Mbps. Big corporations, universities, and research laboratories extensively use B-ISDN interfaces, protocols, and reference models as a WAN at both national and international levels.

Synchronous Optical Network (SONET) and Synchronous Digital Hierarchy (SDH) Standards

The SONET is derived from Bellcore's (now known as Telecordia) Synchronous Optical Network. In the past few years, the telecommunication service carrier companies replaced the existing copper wires by the optical fiber (OF). The plesiochronous digital hierarchy (PDH) is a technology used in networks to transport large quantities of data over digital transport equipment, such as fiber optic and microwave radio systems. PDH allows transmission of data streams that are nominally running at the same rate, but allowing some variation on the speed around a nominal rate. The European and American versions of the PDH system differ slightly in the detail of their working, but the principles are the same. PDH is now being replaced by SDH equipment in most telecommunications networks. Synchronous Digital Hierarchy (SDH) standard includes all the functionalities of SONET. Both SONET and SDH were originally introduced for optical fiber transmission where SDH offers a network node interface (NNI) defined by CCITT/ITU-TS worldwide and is compatible with SONET.

SONET standard was defined by ANSI (American National Standards Institute), whereas SDH was introduced by ETSI (European Telecommunication Standards Institute). The specification and application of SDH and is now being used everywhere outside of North America and Japan. The Japanese version of SDH differs only in some details but is not significantly different than ETSI's. Both SDH and SONET are being used in public networks and offer data rates higher (over 40Gbps). More detailed information on SONET can be found at the International Engineering Consortium (IEC) SONET Web ProForum (for more details, please refer to Hura and Singhal, 2001; Goldman, 2004).

X.25 Packet-Switched Network

In the early 1970s, there were many data communication networks (also known as public networks), which were owned by private companies, organizations, and governments agencies. Because those public networks were quite different internally, and the interconnection of networks was growing very fast, there was a need for a common network interface protocol. In 1976, X.25 was recommended as the desired protocol by the CCITT (now ITU). X.25 was originally approved in 1976 and subsequently revised in 1977, 1980, 1984, 1988, and 1992. It is currently (1996) one of the most widely used interfaces for data communication networks. Various WANs and also LANs use the capabilities offered by X.25 networks.

X.25 (Figure 6) is a packet-switched protocol architecture that defines an international recommendation for the exchange of data as well as controls information between a user device (host), called data terminal equipment (DTE) and a network node, called data circuit terminating equipment (DCE). It utilizes a connection-oriented service that ensures that packets are transmitted in order. X.25 comes with three levels based on the lower three layers of the OSI-RM. The physical level deals with the electrical, mechanical, procedural, and functional interface between the DTE and the DCE. It is specified by the X.21, X.21-bis,

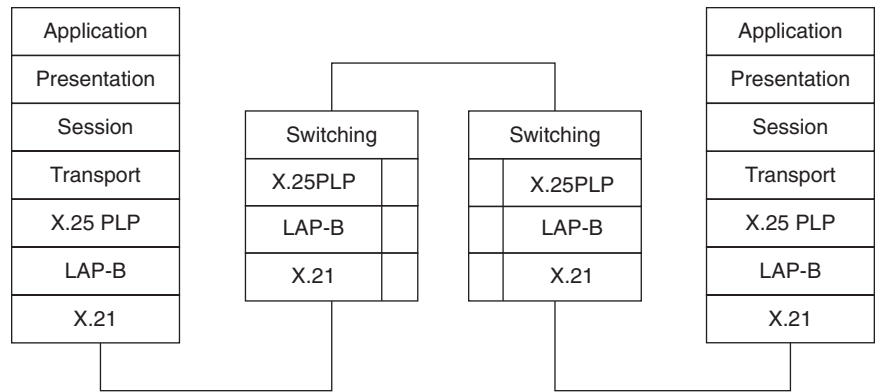

Figure 6: X.25 protocol architecture

and the V.24 recommendation for modems and interchange circuits. The link level (or frame level) ensures reliable transfer of data between the DTE and the DCE by transmitting the data as a sequence of frames (a frame is an individual data unit which contains address, control, information field, etc.). It uses link access protocol-balanced (LAP-B). The packet level (also known as network level) creates network data units called packets that route information and user data and uses packet layer protocol (PLP). In this network, the transport layer is expected to provide end-to-end connection (Clark and Hamilton, 1999; Hura and Singhal, 2001; Goldman, 2004).

Packet Level Protocol: X.25 evolved from standardization work of ISDN in a packet mode transmission service that minimizes the amount of error detection and error recovery within the network. This feature offers minimum delay, higher performance, greater efficiency, and higher throughput by defining a new streamlined communication process of user-to-network interface (UNI). This interface can connect LANs using WANs. The network-to-network interface (NNI) interface defines signaling and management functions between two frame relay networks. Both UNI and NNI are important in asynchronous transfer mode (ATM) model. X.25 uses in-band signaling that forces both call control and data packets to be transmitted on the same channel as virtual circuit packets. The call control packet is used for setting up and clearing of virtual circuits (VCs). It only supports low-speed terminals at 19.2 Kbps and lower. A separate logical connection needs to be established for every data session.

Frame Relay: The frame relay can be considered as a streamlined version of X.25 and thus requires a close comparison with X.25 (as discussed above). Many of digital WANs offer their own error-correcting capabilities and thus, are not dependent on these capabilities of X.25 and even LANs. Frame relay is designed to overcome most of these drawbacks. It supports low speeds of 56 kbps to T1 (1.544Mbps) or even T3 (45Mbps). It uses statistical multiplexing interface for virtual connections at layer 2. It can handle multiple data sessions on a single logical connection. It does not provide any flow-control and error-control link-by-link or hop-by-hop as it expects this to be provided by higher layers. It is based on the assumption that transmission and switching facilities are reliable. Figure 7 shows the lower three layers of frame relay.

Figure 7: Frame relay

Link Access Protocol-Frame (LAP-F): Frame relay network offers two frame modes of services as frame relay and frame switching and both these modes use the same signaling procedures. Because frame switching requires the frame relay network to perform the error-control and flow-control, it offers minimum overhead. Further, the frame relay-based network performs multiplexing and routing at data-link layer as opposed to packet and link layers together performing these functions in X.25 networks. (See the frame relay forum at www.frforum.com or www.protocols.com.) Benefits of frame relay (according to the frame relay forum):

- Savings, greater bandwidth flexibility, greater reliability than private lines
- Allows the consolidation of LAN, SNA, voice, and packetized video
- Smooth migration to ATM
- Low overhead combined with high reliability
- Well-established, widely adopted standards that allow open architecture and plug-and-play

Frame Relay Services: The frame relay packet switching offers higher data rates and suffers very small overhead for communication. It allows multiple calls to different destinations to be handled at the same time by data-link layer. Thus, once a virtual circuit (path) has been established using D channel, a unique identifier is assigned to this circuit. This path is used for all the subsequent frames. This path identifier has a local significance and as such when the frames are traveling over different links is associated with virtual paths identifiers. When frames are received by the frame handler during data transfer phase, it checks the data link connection identifier and combines with all incoming numbers to determine the corresponding

outgoing link and data link connection identifier. It assigns a new data link connection identifier and is forwarded to appropriate outgoing link. This maintains the order of arrival of frames and also the routing becomes faster. The only disadvantage with this switching is the congestion during heavy network traffic over the outgoing links.

Applications of Frame Relay: Frame relay finds its applications in block-interactive data applications (e.g., high-resolution graphics) file transfer, multiplexing of low-bit rate, character-interactive data applications (e.g., text editing), unpredictable, high-volume and bursty traffic applications (e.g., e-mail, computer-aided design/computer-aided manufacturing: CAD/CAM, client-server), and medium-to-large sized networks with mesh or star connectivity. This is not suitable for continuous traffic applications (e.g., co-development, multimedia, transfer of large files of 100 Mbps) and for providing connectivity between dumb terminals and mainframe.

Standardization of Frame Relay: The first specification for standardization of frame relay was introduced to Consultative Committee on International Telegraph and Telegraph (CCITT) in 1984. The frame relay did not get acceptance due to lack of interoperability and missing specifications for standardization. During the early 1980s, a consortium (Cisco, DEC, Northern Telecom, StrataCom) developed a specification that was based on CCITT's standard with added capabilities of complex internetworking environment and named as local management interface (LMI). ANSI (United States) and International Telecommunication Union-Telecommunication Standard section (ITU-T) have subsequently standardized their versions of LMI (www.frframe.com). The frame relay offers a connection-oriented link layer service known as frame relay bearer service (FRBS) (www.protocols.com).

Frame Relay Network: A typical frame relay network looks like as shown in Figure 8. It includes frame relay access equipment; frame relay switching equipment, and public frame relay services.

Access Equipment: This equipment converts data into frame relay packet and does not provide any routing. It is also known as customer premises equipment (CPE) that is being used by frame relay to send information over the

network to data terminal equipment (DTE). This could be any device like terminal, PCs, bridge, router, packet switch, hosts or even frame relay packet assembly/disassembly (PAD) and other similar devices. This device may be used either with a private network frame relay switching equipment or with frame relay services.

Frame Relay Switching Equipment: These devices transport the frame relay frames generated by access equipment. These may be T1/E1 multiplexers, packet switches, or any other equipment that implements standard interface that is capable of switching and routing information received in frame relay format. Because the transmission of frame can be achieved either using variable length size (frames) or fixed length size (cells), the same equipment may be used for creating either private or public frame relay networks. Usually the public service providers (carriers) provide frame relay services by deploying frame relay switching equipment and also connectivity between access and switching equipments. They maintain access to network via standard frame relay interface.

Switched Multi-Megabit Data Service (SMDS)

It is a high-speed and performance, packet-switched, datagram-based WAN used for communication over public telecommunication carrier networks using fiber- or copper-based media and is service independent. It supports speeds of 1.544 Mbps over digital signal level 1 (DS-1) transmission facilities, or 44.736 Mbps (45 Mbps in United States) over digital signal level 3 (DS-3) and 155 Mbps transmission facilities. It allows easy transition from existing LAN interconnects arrangements into leased lines and private switched networks that offer a low transit delay. It has created enormous interest within the United States and Europe to accept this technology as a public service. In fact, British Telecommunication (BT) SMDS pilot project on SuperJANET (<http://www.ja.net/sj5/history.html>) is the preliminary step to the launch of a national SMDS service in the UK. Some of the materials presented here have been derived from Goldman, 2004.

Currently, the SMDS access is based on distributed queue dual bus (DQDB) standard MAN (IEEE 802.6). DQDB is based on fixed-length cells of 53 bytes and as such SMDS packet (variable length) must be broken into

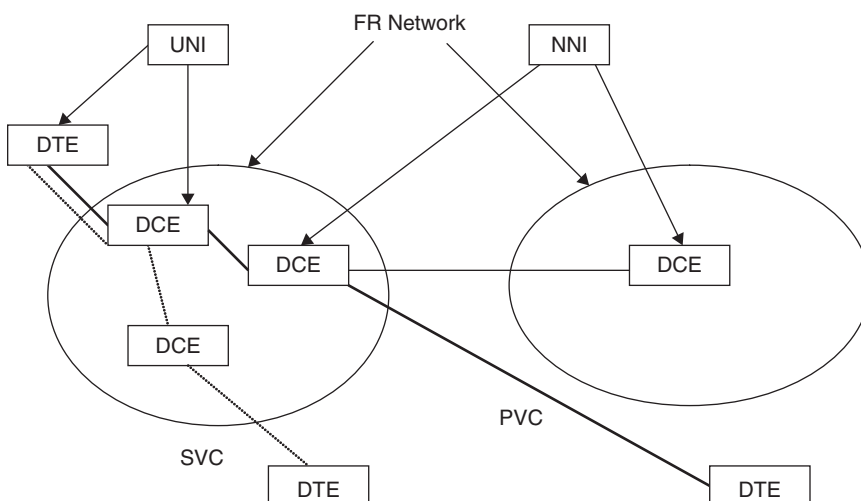

Figure 8: Typical frame relay network

these cells for its transmission over DQDB. The SMDS interface protocol (SIP) defines DQDB-compatible access from a customer site to a network switching site. The Data eXchange Interface (DXI) protocol supports the use of SMDS over serial links, particularly local attachments, and is based on high data link control (HDLC) framing. Both SIP and DXI have been used in a number of pilot projects (e.g., SuperJANET SMDS pilot network) and some attempts have been made to include ATM within SMDS network for offering broadband services.

Features of SMDS include:

1. **Packet network reliability:** In an Ethernet environment, under heavy traffic, packets have a higher rate of collision, and the ability to be lost. The reliability of packets (based on SMDS) for point to point transmission is much higher and is without error or collision.
2. **SMDS security:** Each destination node (CPE) is assigned with one of several address numbers that is specified in destination address field of PDU. The network keeps a multiple copies of PDU that are sent to all the members of group. When the packet is to be transmitted, it is associated with a given destination address. This packet is then sent out over a nonspecific physical path. Each packet takes a different path to get to the destination. This means that there is much less chance for someone to catch all the packets that are sent. This makes SMDS more secure and offers data integrity. SMDS defines a number of nodes on SMDS that can transmit and receive the data and as such define LAN-like environment. It offers fully logical meshed connectivity that in turn supports fault tolerance, whereby a failure of one node does not affect the data transfer within the network. It implements security via address validation and address screening. The former ensures that PDU source address is accurately assigned to the SNI from which it was sent. It prevents address spoofing where illegal traffic assumes the source address of a valid device. The later allows the user to install a virtual private network that filters out the unwanted traffic. The data unit is not delivered if excludes if address is wrong or disallowed.

One of the main drawbacks of this network is that it does not offer any error-control (as a result of connectionless service), flow control, no guarantee of arrival of packets at the destination. Further enhanced overhead occurs for encapsulation that consumes considerable bandwidth as high as 75%.

Applications of SMDS: It found its applications in a limited business arena. One such application that uses SMDS for Internet access is CERFNet (www.cerfnet.com), a subsidiary of General Atomics. A case study was done over the company and their use of SMDS. The focus of the article was to demonstrate that SMDS gives full access to Internet and mail services, support of large usage and broadband requirements, multiple host connectivity, security, high-speed access, privacy, and functionality. Other service industries that are deploying SMDS include banking, insurance, finance, and others that use optical scanning methods for creating electronic file

cabinets for increasing storage capacity and improved access mechanisms.

Standardization of SMDS: Bellcore (now Telecordia) defined the technical specifications of SMDS in the United States and has been adapted in Europe as well (European SMDS Interest Group [ESIG] and European Telecommunications Standards Institute [ETSI]). One of the aims of this specification was to provide a LAN-compatible connectionless (variable length of packets) data service between end users. It supports standard protocols and communication interfaces using the existing technology. Several organizations are active in supporting the development and use of SMDS. A European SMDS Interest Group was formed in October 1991 and SuperJANET is participating as an observer. The focus for SuperJANET SMDS work is the SMDS sub-committee set up by the IP Technical Advisory Group (IPTAG) (www.ja.net, 2006).

SMDS Network: It uses 53 octets (bytes) cell for transport and can accommodate maximum packet lengths of 9188 octets. In general SMDS network requires: Terminal equipment (computers), SMDS channel service unit (CSU)/data service unit (DSU) for SIP Protocol DS1 and DS3 or (1.17 Mbps to 34 Mbps), standard CSU/DSU for DXI DSO (56 kbps), router with SMDS protocol enabled, and network software.

Components of SMDS Network: It consists of customer premises equipment (CPE), carrier equipment, and the subscriber network interface (SNI). CPE includes end devices, such as terminals and personal computers, and intermediate nodes, such as routers, modems, and multiplexers. It is typically owned and maintained by the customer. Intermediate nodes, however, sometimes are provided by the SMDS carriers. Carrier equipment generally consists of high-speed WAN switches that must conform to certain network equipment specifications, such as those outlined by Bell Communications Research (Bellcore and currently known as Telecordia). These specifications define network operations, the interface between a local carrier network and a long-distance carrier network, and the interface between two switches inside a single carrier network. The SNI is the interface between CPE and carrier equipment (Figure 9). The function of the SNI is to offer the technology and operation of the carrier SMDS network transparent to the customer. For details, please

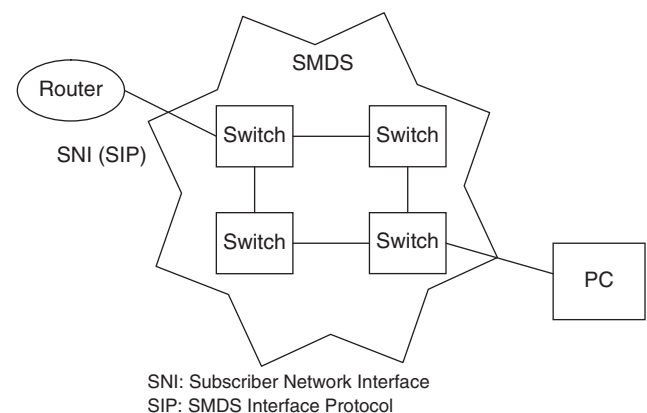

Figure 9: Components of SMDS network

visit www.alpeda.com, www.oreilly.com, www.pacebell.com, and www.cerf.net. It should be noted that the access class restrictions only apply to data transmitted into the network, not to data received from the network. The access class restrictions may result in packets being discarded; connectionless data networks do not guarantee to deliver the packets that are submitted to them and the communicating end systems are expected to be capable of detecting packet loss and recovering from it, for example, by re-sending the packets.

Internetworking of SMDS to LANs: Figure 10 shows how a LAN can be connected to SMDS network. The link between the network switching center and the customer site is provided by either a 2-Mbps megastream connection or a 34-Mbps optical fiber connection using the SIP standard. DXI supports the transmission of SMDS packet over local high-speed link, whereas SPI supports the transmission of SMDS packet in DQDB cell over optical fiber. DQDB (IEEE 802.DQDB) standard is a data-link layer communication protocol designed for use in MAN and consists of two unidirectional logical buses that interconnect multiple systems.

The optical fiber is terminated at each end by an optical line termination equipment (OLTE) providing an optical/electronic interface. On the customer's site, this interface is connected to a DSU, which in turn is connected to a router on a LAN via a high-speed serial media that uses the DXI protocol. The DSU provides conversion between DQDB on wide-area link side and HDLC on the router side. The interface between router and DSU allows routers to interface to a range of high-speed networking services

via a standard hardware interface. Different DSUs are used to provide the specific interfacing requirements for the different services. A range of protocols can be routed over SMDS, including TCP/IP and widely used proprietary protocols. IP over SMDS is specified in RFC 1209.

Internetworking of SMDS to Internet: The Internet is composed of hosts or networks as nodes that provide the communications between end users. SMDS can also be considered as one of sub-networks similar to existing LANs (Ethernet, token ring). SMDS offers service at MAC level (OSI-RM) and as such IP datagram is treated similarly. In other words, both MAC and SMDS will receive the IP datagram that is included within IEEE 802.2 LLC type I (unnumbered information) and sub-network access protocol (SNAP). Customer's premises components include host, subnet (LAN), and gateway. The gateways offer both MAC and SIP protocols. SMDS network uses SMDS interface protocol (SIP) and defined clearly as the boundaries around SMDS (Figure 11).

SMDS does not enforce any minimum size of IP datagram and in fact is being supported by gateway and host. Gateway implementation must accept full-length of IP packets and should avoid fragmentation (if possible). Gateway will handle the address resolution for SMDS users (to be defined as permanent published bindings in a static table) in the same way as it does on X.25 public data networks. SMDS also allows the users to define their private network over Internet using screening features of SMDS. Assignment of unique SMDS group address for its use within IP network or sub-network has been discussed

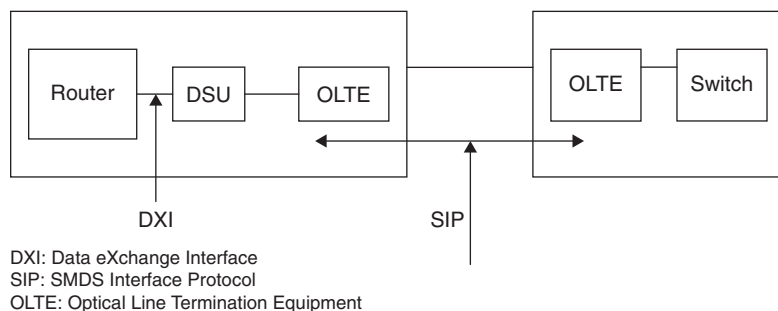

Figure 10: Internetworking of SMDS to LAN

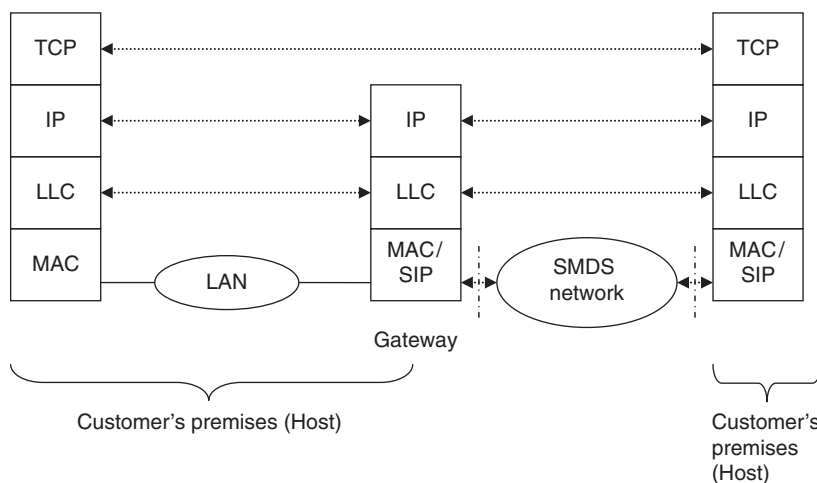

Figure 11: Internetworking of SMDS to Internet

in an SMDS interest group that has been formed within the Internet Engineering Task Force (IETF). SMDS network maintains the quality of service over metropolitan and wide area. It is hoped that the many of the features offered by SMDS will make it useful for a number of distributed processing and multimedia applications.

Asynchronous Transfer Mode (ATM)

One of the promising high-speed networks during 1993 and 1999 has been asynchronous transfer mode (ATM)-based network. This network does not distinguish between the types of networks and uses both circuit and packet switching methods. A fixed size of cell length of 53 bytes is defined, out of which 5 bytes is used for header (per CCITT's recommendations). It provides data rates of 25 Mbps to 155 Mbps and above to various types of application signals like data, voice, video, and images. This integrated switching technique in general is known as cell-based-switching technique and offers connection-oriented services to these applications. It offers a single link-by-link cell transfer capability, which is common to all applications. The higher layer information is mapped into ATM cell to provide service-specific adaptation function on end-to-end basis. It overshadowed DQDB technology around 1993.

The word asynchronous may be confusing. This concept refers to the multiplexing of ATM cells for different types of networks (data, voice, and video) and sends the data associated with these networks on same physical network only when there is a data to send. In other words, ATM is a service-independent network. It is flexible in terms of bandwidth and also efficient (same resources can be used for different types of networks). In contrast to this, in synchronous networks, a special bit packet known as idle must be sent over the channelized network during every time slot corresponding to the channel to keep both sending and receiving nodes synchronous. Further, every channel is assigned with a fixed bandwidth based on its position (time or frequency) and hence is service-dependent (Ginsburg, 1996; Hura and Singhal, 2001; McDysan and Spohn, 1998; Goralski, 1995; www.atmforum.org).

Applications of ATM: With the advent of ATM and its acceptance in B-ISDN high-speed networks, various applications have been developed including distributed multimedia (sales, engineering, and support organizations using multimedia applications over ATM), distance learning (video broadcasting of training sessions will be cheaper than existing satellite technology), video documentation (new CD-ROM technology documenting large volumes of video for sharing over high-speed and high bandwidth ATM networks), medical imaging (transmission, sorting, sharing data from medical imaging devices via high performance network within premises), which may be extended for WANs based on ATM networks.

ATM Cell: A fixed size of cell length of 53 bytes is defined, out of which 5 byte is used for header (Figure 12). It supports both types of data frames or traffic: continuous (PCM voice video applications), and bursty (data from LANs, subnets). It is important to know that ATM cell length is the smallest frame size of 64 byte in Ethernet LAN.

Header (5 bytes)	Payload (48 bytes)
------------------	--------------------

Figure 12: ATM cell

Payload typically contains data but may include some overhead bytes as well.

ATM Transmission: It defines a transfer mode where fixed length of information units with headers are multiplexed onto a transmission media. Each multiplexed channel is distinguished by the attached header. The ATM switching each channel does not have any limit on its speed other than the limit defined by the transmission media. It does not support error-control and flow-control and as such we do not have to synchronize the terminals with that of network for data communications. The ATM multiplexer, in general takes the data from the device (specific number or multiple cells), adds its 5-byte header, and transmits it. In some cases, ATM adaptation layer (AAL) processes the data and adds header and trailer and passes the frame to segmentation and reassembly (SAR). The SAR segments the data into data units, which are then sent to ATM.

The ATM addressing defines two identifiers as virtual path and virtual circuit. The virtual path defines multiple virtual channels to the same end points. The virtual channel is static to destination, whereas virtual paths are different at each node. The virtual path is predefined either through system administration or by signaling protocol. The ATM switching (packet or fast-packet) in fact provides translation of VCI and VPI at switching node or cross-connect node (ATM switching node). It also provides cell transportation between sets of input lines into dedicated output lines. A connection from end-user VCI to end-user VCI is defined as virtual channel connection, whereas end VPI to end VPI is defined as virtual path connection. The physical resources are used on demand and are available only when the data frame is to be transmitted. Each physical link can support a maximum of 256 VPIs at any node and each virtual path can support a maximum 64,000 virtual channels. On other side, NNI can support a maximum of 4096 VPIs.

The transmission of ATM cells through ATM networks goes through various ATM-based components like ATM multiplexers and cross-connect nodes. Obviously, we have to provide synchronization for proper communication for ATM cells. The transfer of ATM cells follows the following sequence of functions: generation of cells, transmission of cells, multiplexing, switching nodes, and switching of cells. The generation of cells mainly deals with the mapping between non-ATM information and ATM information. If the B-ISDN terminals are used, the information is inherently mapped onto ATM cell formats and hence no additional mapping is required.

ATM supports four basic classes of services with an option of offering other variant services around these basic classes as discussed below:

Class 1: Constant bit rate (CBR) service specifies connection-oriented service offering a constant bit rate. AAL0

specifies peak cell rate (PCR), pulse code modulation telephone systems, circuit emulation (transport of 2 Mbps or 45 Mbps) signals. Examples of this service include 64Kbit/sec voice, fixed-rate uncompressed video, and leased lines for private data networks.

Class 2: Variable bit rate (VBR) service specifies an average cell rate that can peak at a certain level for a maximum time. AAL2 supports a connection-oriented service in which the bit rate is variable but requires a bounded delay for delivery. The requirement on bounded delay for delivery is necessary for the receiver to reconstruct the original uncompressed voice or video. It offers real-time and non-real-time variants and typically used for bursty traffic like compressed packetized video and audio.

Class 3: Connection-oriented data service specifies a minimum rate that is guaranteed for connection-oriented data communication. For connection-oriented file transfer and in general, data network applications where a connection is set up before data is transferred, this type of service has variable bit rate and does not require bounded delay for delivery. Two AAL3/4 protocols were defined to support this service class. But with its high complexity, the AAL5 protocol is often used to support this class of service.

Class 4: Connectionless data service allocates unused bandwidth after allocating bandwidth to other traffic, connectionless data. Examples of this service include datagram traffic and in general, data network applications where no connection is set up before data is transferred for unspecified bit rate (UBR). Either AAL3/4 or AAL5 can be used to support this class of service.

ATM Network: The networks based on ATM or fast packet-switching provide no flow-control or error-control and also no dynamics actions are defined for the lost packets. But, preventive actions for error-control are supported by these networks. This does not become a major drawback as these networks work on connection-oriented mode. The establishment of connection during set up phase is defined (based on the request received by networks) before the user data can be transmitted. After this phase, the user data will be transmitted only when the resources are available. After the user data transfer is over, the resources are released. All the networks are defined around some parameters of service and these parameters range from

connectionless, connection-oriented, constant bit rate (CBR), variable bit rate (VBR), quality of service (QoS).

The ATM cell is transmitted as fixed-sized packet of bits at physical layer in contrast to defining a structure of 0s and 1s for a type of service in other existing networks. It integrates data, voice, video, images, and graphics for a higher bandwidth and LAN interconnectivity. This type of connection-oriented mode also provides an optional QoS and less probability of packet loss. The probability of losing a packet during the transmission is very low (typically 10⁻⁸ to 10⁻¹²) and also the allocation of resources is made available with an acceptable probability. A layered model for protocols handling these situations is shown in Figure 13.

Core Functions of AAL: The ATM adaptation layer (AAL) relays ATM cells between the ATM layer and the higher layer. When relaying information received from the higher layers, it segments the data into ATM cells in terms of packet data unit (PDU). When relaying information received from the ATM layer, it must reassemble the payloads into a format the higher layers can understand. This operation, which is called segmentation and reassembly (SAR), is the main task of AAL. Various services classes (1 through 4 as described above) supported by AAL PDU protocol are usually selected from the parameters of QoS and a particular service depends on the set of parameter(s) chosen and the service user. For example, if service user is LLC, the user has selected parameter of QoS for LLC and as such, this user service needs only segmentation and reassembly by AAL protocol (no error recovery as it is supported by LLC itself). But if the user service is X.25 PLP (packet-level protocol), then AAL protocol must provides these core functions: segmentation, reassembly, error detection, and error correction. In the case of user services other than LLC or X.25 PLP, all the functions of AAL are required for user services.

For any of the service users, AAL protocol defines a list of core functions (as discussed above) that will be used and other functions will be provided on the top of these core functions depending on the type of service user selected. The protocol reference model of ATM-based network

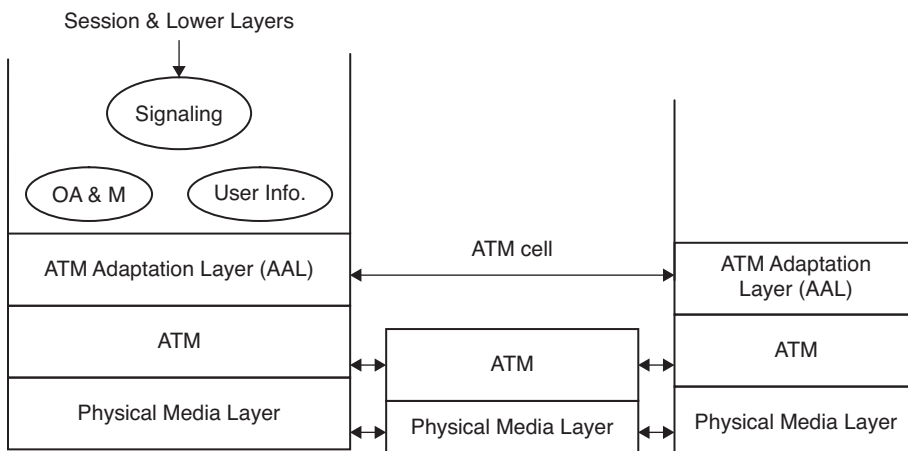

Figure 13: Layered ATM protocol architecture

follows the layered protocol reference model of OSI as shown in Figure 14.

Different AAL PDUs were defined in supporting different traffic or service that is expected to be used. The following section describes the main features of each of these PDUs along with steps required for the transmission of cells through ATM network.

ATM Adaptation Layer 0 (AAL0): AAL0, a connection-oriented service, is useful for applications of constant bit rate sources (CBR), such as voice and videoconferencing and class 1 service. Because AAL0 requires timing synchronization between the source and the destination, it depends on a medium, such as SONET, that supports clocking. AAL0 payload consists of 48 bytes without special field, is also referred to as raw cells.

The AAL0 requires three steps for the transmission of cells over the network. First, synchronous samples (for example, 1 byte of data at a sampling rate of 125 microseconds) are inserted into the payload field after the header. Second, sequence number (SN) and sequence number protection (SNP) fields are added to provide information that the receiving AAL0 uses to verify that it has received cells in the correct order. Third, the remainder of the payload field is filled with enough single bytes to equal 48 bytes.

ATM Adaptation Layer 2 (AAL2): This PDU is perfect for low-rate voice traffic, with compression, silent, and idle channel suppression mechanisms. It is subdivided into the common part sub-layer (CPS) and the service specific convergence sub-layer (SSCS). It handles the bursty traffic (timing requirements), which is also known as variable bit rate (VBR) traffic and class 2. It is suitable for VBR traffic and it uses 44 bytes of the cell payload for user data and reserves 4 bytes of the payload to support the AAL2 protocol. VBR traffic is characterized as either real-time (VBR-RT) or as non-real-time (VBR-NRT). AAL2 supports both types of VBR traffic.

ATM Adaptation Layer 3/4 (AAL3/4): AAL3/4 supports both connection-oriented and connectionless data and

class 3 and 4 services. It was designed for network service providers and is closely aligned with switched multimegabit data service (SMDS). It requires four steps for cell transmission. First, the convergence sub-layer (CS) creates a protocol data unit (PDU) by attaching beginning and end fields at the header and appending the length field as a trailer in the frame. Second, the segmentation and reassembly (SAR) sub-layer fragments the PDU and attaches a header to it. Third, the SAR sub-layer attaches a CRC-10 trailer to each PDU fragment for error control. Fourth, the completed SAR PDU becomes the payload field of an ATM cell to which the ATM layer attaches the standard ATM header.

ATM Adaptation Layers 5 (AAL5): AAL5 is the primary AAL for data that supports both connection-oriented and connectionless data and AAL3/4 with limited error control. It supports error detection only without error recovery. It is used to transfer most non-SMDS data, such as classical IP over ATM and LAN emulation (LANE). It is also known as the simple and efficient adaptation layer (SEAL), because the SAR sub-layer simply accepts the CS-PDU and segments it into 48-octet SAR-PDUs without reserving any bytes in each cell and is used mostly for data traffic. It has no per-cell length or per-cell call CRC fields.

It requires three steps for cell transmission. First, the CS sub-layer attaches a variable-length PAD and an 8-byte trailer to a frame. Second, the SAR sub-layer segments the CS-PDU into 48-byte blocks. A header and trailer are not added (as is in AAL3/4), so messages cannot be interleaved. Third, the ATM layer places each block into the payload field of an ATM cell. For all cells except the last, a bit in the payload type identifier (PTI) field is set to 0 to indicate that the cell is not the last cell in a series that represents a single frame. For the last cell, the bit in the PT field is set to 1.

ATM-based LANs: In ATM-based LANs, the ATM switch sets up a point-to-point ATM communication between nodes and once ATM call is established between nodes, the full bandwidth of 100 Mbps can be used by them. ATM-based LAN may have ATM LAN switches with 16 to 68 connections, internal ATM interface cards for

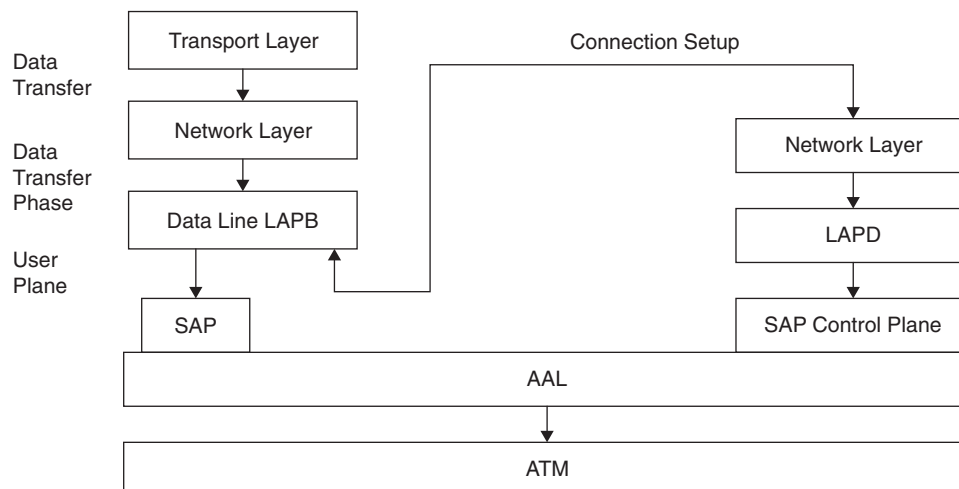

Figure 14: User and control planes for data transfer

nodes (PCs or workstations), and fiber optic transmission medium. The data rate for ATM LAN will be around 100Mbps, which seems to be widely accepted among the members of the forum and may become a de facto standard. Each ATM interface card will provide a direct link between it and the switch and provides 100Mbps full-duplex link between the nodes.

The private networks based on ATM switches can also be defined by defining ATM-based LANs. These LANs configure in the same way as other LANs do, for example, in Ethernet, token ring, token bus, and FDDI. The nodes (PCs or workstations) share the resources by sharing the LAN bandwidth. A typical ATM cell network is shown in Figure 15. In this network, nodes relay cells around the network and layer 2 is known as end-to-end layer and as such supports different types of LANs (802.3, 802.5, 802.4, or any other similar LANs). The network layer uses internetwork packet exchange (IPX) protocol (Novell Network operating system) that offers datagram protocol for connectionless communication. This network seems to offer a better way for interconnectivity, but may not be practical as a result of the fact that the relationship between ATM and OSI-RM layers are still not defined clearly.

Wireless Asynchronous Transfer Mode: ATM has been traditionally used for high-speed applications as it prepares a packet of size (53 byte cell), transmits over network at very high speed. It seems obvious that wireless ATM (WATM) is an emerging and promising technology where ATM cells can also be transmitted over wireless channels. In this environment, part of ATM connection is being provided by wireless network. ATM provides seamless interconnection with backbone ATM networks, supports QoS of wireless and mobile users and small packets over wireless channel. Because ATM cells are transmitted over wireless links, a high rate of cell loss may occur. This cell loss may be reduced by use of forward error-correction algorithms, error-detection schemes (cyclic redundancy control). This may also require buffering, retransmission and re-sequencing of ATM cells. The ATM provides connection-oriented services and as such rerouting needs to be determined when a mobile user moves to new location. It may require setting up a new connection, providing multiple paths to mobile user; forwarding ATM cells or dynamically rerouting the connection. This information should be available to wireless ATM network and also any change in mobile user must be recorded in storage system, location database.

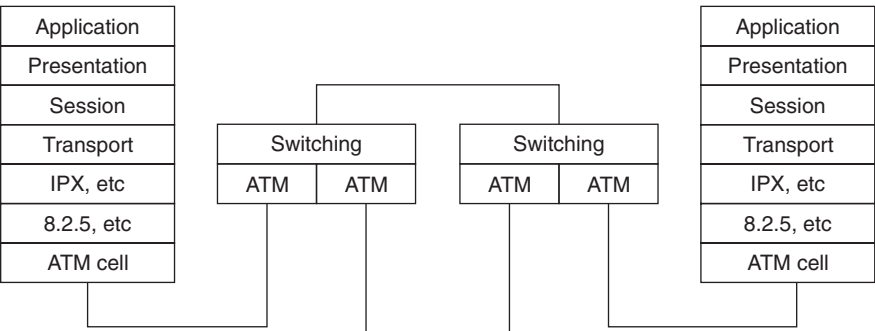

There are many factors that have not made wireless ATM popular and beneficial like cost, lack of standards, and complexity in implementation and amount of overhead. With increased radio bandwidth, emerging reliable and QoS-based protocols, and error-control protocols, it looks very promising that wireless ATM will support mobile users soon.

FUTURE DIRECTIONS

The introduction of a simple and cheap local area network (10 Mbps) solution has led to the development of many technologies dealing with customer premises environments like 100-Mbps and 10-Gbps IEEE LAN, switched Ethernet, and FDDI-II. A new LAN using the standard MAC protocol distributed queue dual bus (DQDB) for a metropolitan area was introduced as a MAN (IEEE 802.6). The evolution of ATM has gone through a number of phases and technologies. In the first phase we have seen 100-Mbps LAN, switched Ethernet, and FDDI-II. The second phase saw the emergence of MANs. A new switching technique known as packet switching was introduced for WANs. The last phase has seen a variety of public network services via technologies of SMDS and frame relay.

Wireless technology has introduced a new concept of networking in which a variety of hand-held devices can be connected. It also allows to be used in different types of networks (LANs, MANs, and WANs). It has also found its application in ATM-based WANs.

SMDS seems to be a matured technology and found its applications in limited business arena. One such application that uses SMDS for Internet access is CERF-Net (www.cerfnet.com), a subsidiary of General Atomics. A case study was done of the company and their use of SMDS and main focus was to demonstrate that SMDS gives full access to Internet and e-mail services, support of large usage and broadband requirements, multiple host connectivity, security, high-speed access, privacy, and functionality. CERFNet explained in the article that because SMDS is technology independent, it is a good way to provide service to customers that use frame relay, FDDI, ATM, and dedicated private lines. The company also felt that because SMDS is a broadband technology that can be compatible with whatever new speed rate is invented, that it would be a technology to stick with. Other service industries that are deploying SMDS include banking, insurance, finance, and others as these use

Figure 15: A typical ATM network

Table 1: Comparison of High-Speed Technologies

Parameters	FDDI	FDDI-II	ISDN	B-ISDN	X.25	Frame Relay	SMDS	ATM
Media access mechanism	Token ring	Token ring	Public Telephone network	Telephone network	Public data network	Public switched data network	Distribute Queue Dual Bus standard (IEEE 802.6)	ATM cell (53 byte)
Switching mechanism	Packet	Packet	Circuit	Circuit	Packet	Packet (frame)	Packet switched datagram over public data networks	Circuit and packet
Transmission media	Optical fiber	Optical fiber	Public telephone network	Optical transmission (fiber optics)	Public telephone network	Public telephone network	Optical fiber, copper	Fiber optics
Data rate	100 Mbps	100 Mbps	144 K–1.54 Mbps (U.S.) 2.56 Mbps (Europe)	155 Mbps (UNI), 622 Mbps (NNI)	Offers UNI and NNI, low-speed terminal at 19.2 Kbps	56 Kbps, T3, 100 Mbps	1.54 Mbps (DS-1)- 44.736 Mbps (DS-3)- 155 Mbps	25–155 Mbps
Features	As MAN, backbone in campus	High performance workstation		Higher bandwidth and data rate over a longer distance, immune to electromagnetic fields	Minimum delay, higher performance and throughput	Minimum overhead, error-control and flow-control	High speed and performance, no error and flow controls	Flexible bandwidth, multiplexing of ATM cells
Types of services	Point-to-point	isochronous	Integrated voice and data	Service independent network	Exchange of data and control between DTE and DCE	Stream-lined control of X.25	Secured network version	End-to-end Service Independent
Network applications	As MAN	High performance processing	Video conferencing	Uses as a WAN	Connection-oriented services	Block interactive data and bursty traffic applications	Limited business like banks, finance, insurance	Distributed multi-media distance learning, video documentation, media imaging
Inter-connectivity	LANs		Public switched data network		Lower layers of OSI-RM	Lower layers of OSI-RM	Public telephone networks	LAN/MAN/WAN
Standardization	IEEE 802 and OSI-RM		T1 (U.S.) 2.56 Mbps (Europe)		International standard	ANSI, ITU-T	U.S. and Europe	U.S., Europe

optical scanning methods for creating electronic file cabinets for increasing storage capacity and improved access mechanisms.

Both LAN technologies (100 Mbps and switched Ethernet) do not guarantee fixed delay for time-sensitive applications, but can deliver the variable length of frames where ATM is preferred for multimedia and video applications. With respect to services, both FDDI-II and ATM can be used, but FDDI-II would be cheaper than ATM. There is close relationship between ATM cell and DQDB slots. MANs are used as a public network for data and offer two advantages over private networks as ubiquity and reliability. The first advantage allows the users to send data to anyone that subscribes to public service (e.g., public voice telephone networks). ATM and SONET offer new technologies, whereas SMDS offers a service and in fact is public service extension of LAN and MAN services.

The Internet is still going strong for offering connections between remote computers and within a few years, these computing devices will be replaced by hand-held and mobile devices, which are expected to create a huge market for cellular phones and PDAs that offer a variety of services. A large amount of research is currently being done in the areas of wireless LANs, wireless PANs, satellite-based networks, wireless local loops (WLL), and wireless ATM, mobile computing, addressing and transport protocols for e-commerce, and GSM and PCS cellular phones.

In summary, it looks obvious that ATM networks can be used for providing LAN emulation, SDMS connectionless, and frame relay services all on the same network. Further, it also supports interconnectivity between these services. So why should we not build one network based on ATM? ATM uses the same procedures and protocols of LANs, MANs, and WANs and provides support for multimedia services. It offers these services at different media speeds and offers virtual connections as opposed to fixed physical channels in other networks. We can get the SMDS services over frame relay networks and vice versa.

ACKNOWLEDGMENT

I thank the following graduate students who helped me in writing this chapter—Jirafe Sameer, Kadri Ravi Kumar, Kifle Eyoel, Pranathi Yerragudi, and Susnerwala Abdul. I also express my sincere thanks to anonymous referees who have provided me with many positive and constructive suggestions/comments to improve the quality of this chapter.

GLOSSARY

Asynchronous Transfer Mode (ATM): This mode is defined for B-ISDN and supports different types of signals (data, voice, video, images).

ATM adaptation layer: This layer is above the ATM layer and provides interface between higher layers and ATM layer. It performs signaling, segmentation, and reassembly on ATM cell.

ATM cell: This interface can handle both types of traffic with unlimited bandwidth and high data rates.

Bridge: This interconnecting device provides interconnection between similar or different types of LANs and is connected at MAC sub-layer.

Broadband Integrated Service Digital Network (B-ISDN): This service independent network transports different types of services (asynchronous, synchronous, and isochronous traffic).

Bursty: An irregular signal distributed over time and denotes a type of noise.

Channel Service Units/Data Service Units (CSU/DSU): A pair of channels (CSU) and (DSU) is used to provide an interface between computer and digital switch of digital network.

Customer Premises equipment (CPE): CPE includes end devices, such as terminals and personal computers, and intermediate nodes, such as routers, modems, and multiplexers. It is typically owned and maintained by the customer.

Distributed Queue Dual Bus (DQDB): A standard MAC protocol for LAN/MAN and supports connection-oriented, connectionless, and isochronous simultaneously.

Ethernet: One of the most common and popular LANs.

Fiber Distributed Data Interface (FDDI): This is a high-speed LAN and is based on fiber optic supporting a data rate of 100 Mbps.

Gateway: This interconnecting device connects heterogeneous networks and works at lower three layers of OSI-RM.

Integrated Services Digital Network (ISDN): A digital network that transmits data, voice, and images together over the same link.

Link Access Protocol-B (LAP-B): This standard is a subset of HDLC that controls data exchange between DTE and public switched networks.

Metropolitan Area Network (MAN): This is a high-speed LAN that offers a data rate of over 100 Mbps within a metropolitan city (around 100 miles)

Plesiochronous Digital Hierarchy (PDH): The commonly used digital hierarchy for synchronous transmission networks and is very popular in Europe.

Switched Multi-megabit Data Services (SMDS): The network is based on concept of fast packet switching and offers broadband services to LANs and WANS.

Synchronous Digital Hierarchy (SDH): Two popular interface data rates for B-ISDN based on ATM are 155.520 and 622.080 Mbps.

Synchronous Optical Network (SONET): This standard is very popular in North America and is a new form compatible with the international SDH.

INTRODUCTION TO PACKET SWITCHING

Packet switching is the dominant communication technology in modern data networking and telecommunications. In previous chapters, the concepts of computer networks were introduced and different type of networks were described based on scale, connection method, functionality, topology, or services. The communication between computers or devices involves the term *switching*, which describes how information is exchanged between the input ports and output ports at each network element.

There have always been two fundamental and competing switching technologies in communications: *static allocation* and *dynamic allocation* of the transmission bandwidth. The public switched telephone network (PSTN) is a typical circuit-switched network, where a fixed bandwidth is pre-allocated for the duration of a call. The early radio system, that is the advanced mobile phone systems (AMPS), is also circuit-switched where the radio spectrum is pre-allocated during a mobile call. On the other hand, message, telegraph, and mail systems have been operated by dynamically allocating bandwidth or spaces after a message is received at the time. They never attempt to schedule bandwidth or space over the end-to-end source to destination path.

There are three major switching techniques, that is, *packet switching*, *circuit switching*, and *message switching*. In packet switching, packets (units of information block) are individually routed among nodes over data links that are shared by many other nodes in the data networks. In contrast with circuit switching that pre-allocates the transmission bandwidth for a user, packet switching allocates the transmission bandwidth dynamically, permitting many users to share the same transmission link previously required by one user. This improves the transmission efficiency especially when users transmit at variable bit rates. Packet switching optimizes the usage of the bandwidth available in a network and saves the transmission cost. It also improves the reliability and functional flexibility of packet delivery in communication networks. Packet switching has been so successful and become the exclusive

communication paradigm in all the data networks built throughout the world. In this chapter, we describe the fundamentals, history and evolution, and key techniques of packet switching.

FUNDAMENTALS OF PACKET SWITCHING

Packets

A *packet* is a block of data that carries user information exchanged over a communication link. It usually consists of three elements: *header*, *payload*, and *trailer*, as shown in Figure 1. The first element, *header*, contains address and administrative information that allows the packet be delivered by the network nodes from the source to the destination. The second element, *payload*, contains the user information that needs to be exchanged in the network. The third element, *trailer*, usually contains information for error detection, allowing receivers to verify that packets do not have errors during transmission. (If errors occur during transmission and cannot be corrected, the packet is usually discarded.) Sometimes, a packet may not have a trailer. The payload together with the header contains all the information needed for packet delivery.

A packet is analogous to a letter (payload) sent through the mail (network) with the address (header) written on the envelope.

Unlike a message (in message switching), the length of a packet is limited and can vary between successive packets. Packets are usually transmitted via frames, which are either fixed-length or variable length data blocks transmitted over the actual physical links. Sometimes packets and frames are interchangeable in some places but they actually have different meaning. Packets are usually referred

Header	Payload	Trailer
--------	---------	---------

Figure 1: The format of a packet

as the transmission unit at layer 3 or the network layer, in a layered network protocol stack, whereas frames are usually referred as the transmission unit at layer 1 or layer 2, the physical layer or the link layer (Tanenbaum 1981).

Nodes

A *node* is a physical device that is connected as part of a data network. Nodes can be personal computers, workstations or servers, specialized data processors, cell phones, personal digital assistants (PDAs), or various other network appliances. Depending on their functionalities, nodes can be characterized in different types. For example, in the SNA (systems network architecture) network architecture invented in early stages of computer networks (Cypser 1978), there are four type of nodes defined. Type 1 nodes are terminals. Type 2 nodes are controllers, machines that supervise the behaviors of terminals. Type 4 nodes are front-end processors, devices that relieve the main CPU of the processing and interrupt handling in data communications. Type 5 nodes are the main hosts themselves. There are no type 3 nodes. Nodes that route data for the other network devices as well as themselves are sometimes called super-nodes.

Packet Switching

Circuit Switching and Packet Switching

Computer-to-computer communication has some fundamental differences from human-to-human communication. When you or your telephone places a telephone call, the switching equipment at the central office attempts to allocate a physical path all the way from the caller's telephone to the called telephone. This switching technique is called *circuit switching*. Figure 2 shows a simplified schematic model of circuit switching. In this example, there are multiple switching elements between the two telephones. Each switch has the same number of incoming lines and outgoing lines. When a call is placed through a switch, a physical connection is established between the incoming ports and outgoing ports. The dotted line shows the allocated physical path between the two end points. This dedicated link exists during the entire phone conversation. An important property of circuit switching is that it needs certain time to setup an end-to-end connection

before any information can be sent. This is usually called the call setup time. Once the connection is established, the data transmission delay is only the propagation time, which is quite small.

In contrast to circuit switching, packet switching does not require any dedicated link or path be established in advance between sender and receiver. Instead, the user's overall message is broken up into a number of small packets, each of which is sent separately. Figure 3 shows a simplified schematic model of packet switching. Each packet of user information is labeled to identify its source and destination before it is sent. Each packet is stored at the receiving switching office and then forwarded later, one hop at a time. The receiving end re-assembles the packets in their proper order, with the assistance of the sequence number and other administrative information stored in the header and trailer fields. A network uses this *store-and-forward* technique and allocates the most efficient route available at the time for each packet.

Packet Switching and Message Switching

Yet another alternative switching technique is message switching. Message switching is very similar to packet switching, where there is no need to establish a physical path or link in advance between both ends. Compared to packet switching, message switching puts no restriction on the block size. In other words, the entire message is the transmission and switching unit at each switch. As a result, the switch needs to have large buffer or memory size to store and forward a large message, resulting in a longer queueing and transmission delay and reduced throughput. The advantage of message switching is that it maintains the complete message delivery from sender to receiver. Data networks are usually packet switched instead of message switched. More descriptions on message switching are provided in a subsequent chapter.

Circuit switching and packet switching differ in many respects. The key difference is that circuit switching statically reserves the required end-to-end bandwidth before any data can be sent. Any unused bandwidth on an allocated end-to-end circuit is just wasted. Packet switching acquires and releases the required bandwidth on a packet-by-packet basis. The unused bandwidth for a user's traffic may be utilized by packets from other unrelated users going to different destinations. Therefore,

Figure 2: Circuit switching

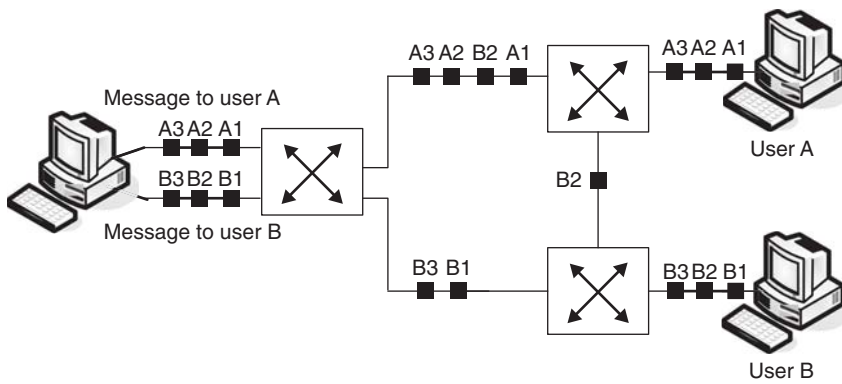

Figure 3: Packet switching

packet switching utilizes the network bandwidth more efficiently than circuit switching.

Because there is no dedicated circuit or path for a user's traffic, packets may be routed by each network node on different routes at the time. Packets may be delivered out of order to the destination with packet switching. Reordering of packets can never happen with circuit switching.

Transmission capacity between pairs of nodes in a packet-switched network is generally not split up into separately physical channels, each of which has a fixed bandwidth. Instead, the entire available bandwidth between pairs of nodes is treated as a single high bit-rate pipe and shared by all the packets sent on the link. In this way, individual packets are transported more quickly, that is, at full speed of the line rate, and bursts of transmission can be accommodated.

A problem occurs when more than one data sources try to send packets at the same time exceeding the bandwidth of the data link. This situation is accommodated by buffers at both sending and receiving ends of the connection between pairs of nodes. The use of buffers smoothes out the burstiness of the traffic and improves the link utilization. This is achieved by *statistically multiplexing* the packets from different sources sharing the same link. The statistical average total bit-rate must be slightly lower than the link bit-rate so that there is no packet dropping as a result of buffer overflow.

The charging algorithms between the two switching technologies are different. In a circuit-switched network, carriers charge the clients based on the connection time and transmission distance. In a packet-switched network, carriers charge the clients based on both the time and number of bytes or packets carried. Transmission distance usually does not matter except when it involves the network layout internationally.

EVOLUTION OF PACKET SWITCHING

Before the modern advances in computer technology and digital signal processing, systems with dynamic allocation were necessarily limited to non-real time communications, because many manual sorting and routing decisions were required along the source to destination path of each message. In late 1960s, virtually all interactive data communication networks were circuit switched, the same as the telephone network. Interactive data traffic occurs in short bursts and thus 90% or more of the static

allocated bandwidth is wasted. The rapid advances in technology evolution have made digital electronics with fast processing power inexpensive enough for a complete redesign of communication networks. The "packet-switching" concept was introduced to make the dynamic allocation systems superior to static allocation systems in terms of cost, connection time, transport efficiency, reliability, and flexibility. As a result, packet switching has become the dominant paradigm in modern communication networks and offered substantial economic and performance advantages over the conventional systems.

History of Packet Switching

Packet switching was evolved from the basic dynamic allocation technique used for conventional mail, telegraph, and paper tape switching systems. Bandwidth is allocated only when a block of data is ready to be sent, and only enough for that particular data block to be transferred over the data link at the time. Depending on the traffic characteristics of the data being transferred, packet switching is generally more efficient (3-100 times more) than static allocation approaches, because it can reduce the wasted available bandwidth resources. This is achieved by adding both processing power and buffer storage resources at each network switch along the path. The economic trade-off between circuit switching and packet switching is obvious: if the bandwidth is cheap, use circuit switching; if computing is cheap, use packet switching.

The first published description of the so-called packet switching was an 11-volumn analysis, *On Distributed Communications*, written by Paul Baran of the Rand Corporation in August 1964 (Baran 1964). It proposed a fully distributed packet-switching system to provide for all military communications of data and voice. The RAND's proposed packet-switching system not only achieved the original goal but also projected superior economics for both voice and data communications.

Independently Donald Davies from the National Physical Laboratory (NPL) in the United Kingdom conducted detail design of a *store-and-forward* packet switching system. The first official publication of the NPL proposal was in October 1967. Davies' original proposal, developed in late 1965, was very similar to the actual networks being built today in almost all respects. His cost analysis demonstrated strong economic advantages for the packet-switching technique.

Baran's study had its influence to Robert Taylor and J. C. R. Licklider from the Advanced Research Projects Agency (ARPA). The interesting discussions motivated Lawrence Roberts to initiate the first two actual network projects. Merrill and Roberts (Roberts and Merrill 1966) did an experiment of connecting the TX-2 computer in Massachusetts to the Q-32 computer in California with a low-speed dial-up telephone line creating the first wide-area computer network. This experiment realized that time-shared computers could work together, running programs and retrieving data on the remote machine.

ARPANET is the creation of ARPA (now DARPA), the (Defense) Advanced Research Projects Agency of the U.S. Department of Defense. The design proposal, which was published in June 1967, consisted of a packet-switching network, with minicomputers at each computer site as the packet switches and interfacing devices, interconnected by 50 Kbps leased lines. The original ARPANET was an experimental four-node network that became operation in December 1969. Each minicomputer took blocks of data from the computers and terminals connected to it, subdivided the data into 128-byte packets and added a header specifying the source and destination addresses. The minicomputer used a dynamically updated routing table to send the packets over the most free line with the fastest route toward the destination. Upon receiving a packet, the next minicomputer would acknowledge it and conducted the same routing process independently from the previous node. Therefore, ARPANET (Roberts 1974; Roberts 1978) was a completely distributed network with a dynamic routing algorithm on a packet-by-packet basis. Much of our present knowledge of networking is a direct result of this pioneering work.

INTERCONNECTION IN PACKET-SWITCHED NETWORKS

Packet-switched network is a fully distributed system that dynamically routes the packets based on a continuous evaluation of the delay on the path, line availability, and queue length at the network node. The interconnection of numerous networks of different types or the connections within a network requires the physical devices that have different functionalities and purposes to serve the network.

Interconnection: Switches, Bridges, Routers, and Gateways

Switches

A switch is a computer networking device that channels incoming data from any of the multiple incoming physical ports to a specific output port toward its destination.

Switches are used in both circuit-switched networks and packet-switched networks. In the traditional circuit-switched telephone network, one or more switches are used to set up a dedicated connection or circuit for an exchange between two or more parties. A *telephone exchange* or *central office* houses equipment that is commonly known as simply a *switch*, which is a piece of equipment that connects phone calls. It makes phone calls “work” in the

sense of making connections and relaying the speech information. In a packet-switched network, for example, in the Ethernet local area network (LAN), a switch examines the physical device's media access control or MAC address in each incoming packet and determines which output port to forward the packet. Figure 4 illustrates a simplified structure of a switch matrix in a central office. All the outgoing trunk circuits (numbered 1 to 4) may be accessed by any of the customer lines (marked A to D). Figure 5 illustrates a simplified internal structure of a packet switch device. It consists of a bus, or multiple buses, connecting together each of the incoming and outgoing ports. Packets received from any of the incoming ports are first stored in the buffers. The switching logic analyzes the address in the packet header and decides which outgoing port the packet is sent to.

A switch usually uses *store-and-forward*, or *cut-through* forwarding method. In store-and-forward method, the switch receives and buffers each frame entirely, typically performs a checksum on the frame, and then forwards it on the output port. In cut-through method, the switch only checks the frame's physical layer address and then forwards it to the output port. It does not do any error checking on the frame.

A switch only connects data from an incoming port to an output port. It does not monitor the traffic because each port is isolated, and only the sending and receiving ports are connected when they transmit the data. Two common methods, that is, *port mirroring* and *switch monitoring* (SMON), were specifically designed to allow

Figure 4: Switch matrix in an exchange office

Figure 5: Packet switch internal structure

a network manager to monitor the traffic in a network with switches. In the port mirroring method, a switch sends a copy of network packets to a monitoring network connection so that the network manager can collect the information and monitor the traffic. The SMON (RFC 2613) is a protocol defined by the IETF RFC 2613 for controlling the interfaces and facilities between the switches and network managers for port mirroring.

Bridges

A bridge is a computer networking device that connects multiple network segments along the data link layer to operate as a single network. It works by using bridging as what its name entails, by connecting two sides of the adjacent networks. It forwards the traffic from one network to another network.

A bridge has intelligence built in the hardware to determine which packets should be transferred into another network. It examines the addresses (indicating a destination service access point and a source service access point) in the *logical link control* (LLC) header of each packet and transfers the relevant packets to the second network directly or via a second bridge. If the physical structure of the two networks is different, for example, one network is an Ethernet, the other is a token ring as shown in Figure 6, the bridge will transform the packet into the right format.

Primitive bridges are relatively cheap. They provide a very economic means for self-configurable interconnection. However, bridges have some limitations of their usage and functionalities. They do not limit the scope of broadcasts and do not scale to large networks. Bridges result in very complicated topologies that are extremely difficult to manage. Thus bridges are not recommended for large and complex networks. Instead, the *router* appears and is used to provide a more complex and intelligent functionality of interconnection in packet-switched networks.

Routers

A router is a computer networking device that forwards data packets across the network toward their destinations based on the routing algorithms. A router acts as a junction between two networks and transfers data packets between them (see Figure 7). Routers are more intelligent than switches and bridges. They are designed to “learn” the topology of complicated networks that are constantly changing and expanding and determine the “best route” for packets or packet flows to their destinations. The key design of routers is the routing algorithm. Routers can learn the network topology through experience, that is, the previous successful routes, and update the routing table accordingly.

Figure 6: LAN bridge

There are different options when designing a network. One option is to put multiple segments into one bridged network. Another option is to divide the network into different sub-networks interconnected by routers. If a host moves between segments in a routed network, it has to get a new IP address and therefore break the transport layer connections, that is, TCP/IP connection. If the host moves in a bridged network, it does not have to reconfigure the packet format and thus is simpler and more economic. The drawback of a bridged network is that it lacks the intelligence and scalability in large and complex networks.

Gateways

A gateway is a computer networking device for interfacing with another network that uses different protocols. It is also called a protocol converter and can operate at any layer of the network model. The function of a gateway is much more complex than that of a router or switch. Typically, a gateway must convert one protocol stack into another.

A gateway may contain devices such as protocol translators, impedance matching devices, rate converters, fault isolators, or signal translators as necessary to provide system interoperability. It also requires the establishment of mutually acceptable administrative procedures between the two networks. A protocol translation/mapping gateway interconnects networks with different network protocol technologies by performing the required protocol conversions.

For example, a gateway may connect a local area network (LAN) or wireless LAN (WLAN) to the Internet or other wide area network (WAN). In this case the gateway connects an IPX/SPX (the LAN) to a TCP/IP network (the Internet), as shown in Figure 8.

Gateways that connect two IP-based networks, like TCP/IP, have two IP addresses, one on each network. An address like 192.168.1.xxx is an address in LAN, to which traffic is sent from the LAN. The other IP address is an

Figure 7: Network router

Figure 8: Gateway connecting two different networks

address in WAN, to which traffic is sent from the WAN. When talking about the gateway IP address, it commonly means the address of the gateway in LAN.

The addresses of computers connected to the LAN are hidden behind the gateway. This means that the WAN can only see the gateway's IP address. To regulate traffic between the WAN and the LAN, the gateway commonly performs network address translation (NAT), presenting all of the LAN traffic to the WAN as coming from the gateway's WAN IP address and doing packet sorting and distribution of return WAN traffic to the local area network.

MAIN TECHNIQUES IN PACKET SWITCHING

X.25

X.25 is the first international standard recommended by International Telecommunications Union (ITU) for packet-switched networks. It was developed in the early stages of packet networks evolution for the nations to agree on a standard user interface to the networks to facilitate network interconnection and permit easier user attachment. X.25 has been widely adopted and used in most packet switched networks.

The X.25 recommendation defines the protocols between a *data terminal equipment* (DTE), for example, personal computer or computer terminal controller, and a *data circuit terminating equipment* (DCE), for example, the connection point to a packet-switched network, as shown in Figure 9. It defines protocols corresponding to layer 1 (physical layer), layer 2 (link layer), and layer 3 (packet layer) in the International Standard Organization (ISO)'s Open System Interconnect (OSI) model.

The physical layer connection may either be X.21 for digital leased line or X.21 bis for V.24/V.28 modem in conjunction with an analogue leased line. The X.25 protocol provides for the data blocks for up to 4095 *virtual circuits* (VCs) on a single full-duplex leased line interface to the network. It includes all procedures for call setup and tear-down. One important feature of this interface is the notion of independent flow control on each VC. The flow control enables the network and the user to regulate the traffic on the flow to protect itself from congestion and overflow. In early networks like ARPANET that did not have the flow control capability, the network had to depend on the host to insure that no user transmitted more data to the network than the network could handle. The network had to shut off the entire host interface if congestion happened, which could be disastrous to other users communicating with the host or network.

Another significant aspect of X.25 is that it defines both layer 1, layer 2, and layer 3 protocol interfaces. These protocols are called the *link access procedures* (LAP) and the *packet level interface*. The link access procedure assures the correct delivery of data across the link connecting a DTE to an DCE for multiplexing of logical channels. The packet level interface guarantees the end-to-end delivery of data across the entire network.

The *link access procedures balanced* (LAPB) protocol provides for the balanced class of procedure and also allows making a single logical link using multiple physical circuits. The link access procedure uses the principles and terminology of *high-level data link control* (HDLC) as defined by ISO. HDLC provides error checksum and ensures the error-free transmission of data information across the link from a DTE to a DCE. However, it does not determine where the information should be forwarded by the DCE within the network, nor ensure its correct delivery at the destination in the packet network. This function is handled by the OSI layer 3 protocol, that is, the X.25 packet level interface.

After X.25 was adopted in March 1976, many additional standards have been agreed on and developed as well, all patterned around X.25. For example, X.31 has been adopted as the standard interface for physical layer connection between a DTE and DCE via an integrated services digital network (ISDN). X.32 specifies the use of dial-up connection for a packet mode connection via the telephone or ISDN network to an X.25 exchange. Finally, X.75 defines the standard protocol for connecting international networks.

Frame Relay

Frame relay is a standard protocol for fast packet switching in LAN. It has much less overhead than the earlier X.25 networks and operates more efficiently. Packets vary in length and are called frames for this protocol. Erroneous or bad frames are discarded instead of retransmitted and thus packets are switched more quickly. Frame relay began its commercial service in 1992 and is now widely deployed.

Standards for the frame relay protocol have been developed by American National Standards Institute (ANSI) and International telephone and telegraph consultative committee (CCITT), now known as ITU-T simultaneously.

Frame relay is essentially an enhancement of X.25, taking advantage of the widespread implementation of fiber optic communication links by long-distance carriers. Fiber is much less prone to introducing errors in a data stream. Therefore frame relay does not use the

Figure 9: X.25 data network structure

extensive error checking in X.25 at the switching nodes. The error-handling processes are instead completed by the sending and receiving devices.

The frame relay frame is transmitted to its destination using the concepts of virtual circuits as in X.25, that is, logical paths from an originating point in the network to a destination point. Virtual circuits may be permanent (PVCs) or switched (SVCs). PVCs are set up administratively by the network manager for a dedicated point-to-point connection. SVCs are set up dynamically on a call-by-call basis. Because virtual circuits consume bandwidth only when they are used to transport data, many virtual circuits can exist simultaneously across a given transmission line. In addition, each device can use more of the bandwidth as necessary, and thus operate at higher speeds. Frame relay is designed to operate at speeds up to 1.5 Mbps, and may be enhanced to operate at higher speeds.

Frame relay is particularly well-suited to the interconnection of LANs that generate bursty traffic consisting of variable-length frames of data. Frame relay accepts this traffic as is, adding only a wide area network address at the front and its own check sequence at the end of each frame. Frame relay interfaces for customer premise equipment such as routers, bridges, and hubs are available from a number of vendors.

Frame relay switches are also available, and numerous carriers offer public frame relay services. As the technology and standards are refined and carrier tariffs are clarified, frame relay networks are expected to replace many X.25 networks during the next several years. However, frame relay is not well-suited to the transmission of real-time voice or video, because of the variable delay allowed between frames.

ATM

ATM stands for asynchronous transfer mode. ATM is a high-speed advanced packet-switching scheme. ATM makes all its packets one length, i.e., the so called *ATM cells*. Each cell has 53 bytes, 48 bytes of data, and 5 bytes of header information. These uniformly small packets or cells let data flow smoothly. ATM also boasts improved error control compared to conventional packet switching, as well as numerous other features that make it a core technology of data networks.

ATM was initially designed to provide a single unified networking standard that could support both synchronous channel networking and packet-based networking (IP, frame relay, and so on), whilst supporting multiple levels of *quality of service* (QoS) for packet data. It was intended to resolve the conflict between circuit-switched networks and packet-switched networks by mapping both bit streams and packet streams onto a stream of small fixed-size cells tagged with virtual circuit identifiers. The cells are typically sent on demand within a synchronous time-slot pattern in a synchronous bit-stream. The asynchronous part here is the sending of the cells, which does not need to follow any synchronous pattern.

In its original conception, ATM was considered as the enabling technology of the broadband integrated services digital network (B-ISDN) that would replace the existing PSTN. The full suite of ATM standards provides definitions

for layer 1 (physical connections), layer 2 (data link layer), and layer 3 (network) of the classical OSI seven-layer networking model. Standards that define ATM networks are established by two different organizations, the ITU and ATM Forum. ATM Forum is an industry consortium that is focused on ATM. The activities of this organization included setting of the technical standards for ATM networks and facilitating the market adoption of the ATM technology. Although the two organizations frequently use different terminology to describe the ATM systems, they present the same concepts of ATM.

ATM Transport and Switching

There are two layers relate to ATM functions and transport, that is, an ATM layer that handles packet transfer and switching capabilities, and an ATM adaptation layer (AAL) that handles specific services and mapping to ATM transport. The ATM layer defines the transmission of data in the format of cells and also the use of logical connections. The ATM layer is further divided into two switching levels supported in the network.

- **Virtual channel (VC):** A VC is a generic term representing the unidirectional transport of ATM cells. The cells carried over a specific VC are identified by a Virtual channel identifier (VCI).
- **Virtual path (VP):** A VP is used to describe a bundle of VCs. The VCs associated with a VP are transported over a transmission path within the network as a group. A VP is identified by a virtual path identifier (VPI).

The VPI and VCI values are carried in the header of an ATM cell, and are used for routing and switching the cell across the ATM network.

The ATM transport creates the need to define an adaptation layer to support specific services and map other transport protocols to ATM. The AAL maps higher-layer data to ATM cells and retrieve data from ATM cells for delivery to higher layers. The general services provided by AAL are: transmission error handling, segmentation and reassembly, flow control and timing control, handling of lost and misinserted cells. The AAL layer is further divided into two logical sub-layers.

- **Convergence sublayer (CS):** The CS provides the functions needed to support specific services and applications using the ATM transport. The CS is service and application dependant. Each user attaches to AAL at a service access point (SAP). The SAP is simply the address of the user application.
- **Segmentation and reassembly sublayer (SAR):** The SAR sublayer provides the functions of generating cells with the data received from CS and retrieving the data from the cells for delivery to CS.

There are five different protocol types defined for the class of services supported by ATM, that is, AAL Type 1, AAL Type 2, AAL Type 3/4, and AAL Type 5. Each protocol type supports specific class of service. For example, type 1 is used to support constant bit rate (CBR) service. Type 2

is used to support variable bit rate (VBR) service. For detailed descriptions of each protocol type and packet format, the readers can refer to the chapter on ATM.

ATM Switching Concept

As described earlier, the ATM layer consists of VC and VP sub-layers that form the basis of switching in ATM networks. There are correspondingly two levels of ATM connection:

- Virtual channel connection (VCC): A VCC extends between points where adaptation layer functionality is performed. The basic function of the adaptation layer is to format data for transport over an ATM connection on the sending end and extract data at the receiving end. These points are VC connection end points.
- Virtual path connection (VPC): A VPC extends from the point at which VCs are assigned with VCI values and associated with a VP, to the point where VCs are removed from the VP or have their VCI values modified. These end points are referred to as the VP connection end points.

VC and VP connections are established by the permanent VC (PVC) by a network operator manually, or the switched VC (SVC), established on demand by signaling procedures between the connection end points.

ATM provides a highly complex technology, with features intended for applications ranging from global telecommunication networks to private local area computer networks. ATM has been a partial success as a technology, with widespread deployment, but generally only used as a transport for IP traffic. Its goal of providing a single integrated technology for LANs, public networks, and user services has not been achieved.

TCP/IP

The Internet protocol suite is the set of communications protocols that implement the protocol stack on which the Internet and most commercial networks run. The TCP/IP protocol suite has the two most important protocols: the transmission control protocol (TCP) and the Internet protocol (IP).

TCP and IP were initially developed by a research project for the Department of Defense (DOD). The goal was to connect a number of different networks from different vendors into a network of networks (the so-called "Internet"). The Internet protocol suite includes not only lower-level specifications (such as TCP and IP), but also specifications for common applications such as electronic mail, terminal emulation, and file transfer. Several computers in a small department can use TCP/IP (along with other protocols) on a single LAN. The IP component provides routing from the department to the enterprise network, then to regional networks, and finally to the global Internet. A communication network needs to sustain damage on a battlefield. Therefore, the DOD designed TCP/IP a robust protocol suite that has the capability of automatically recovery from any node or phone line failure. This design allows the construction of very large networks with

less central management. However, because of the automatic recovery, network problems can go undiagnosed and uncorrected for long periods of time.

TCP

TCP is a connection-oriented transport protocol that sends data as an unstructured stream of bytes. IETF RFC793 defines the transmission control protocol (TCP).

TCP provides a reliable stream delivery and virtual connection service to applications via the use of sequence numbers and acknowledgment messages. TCP can provide a sending node with delivery information about packets transmitted to a destination node. A three way handshake between the source and destination node in TCP sets up the protocol states properly. The retransmission protocol ensure that the data be delivered successfully to the destination. If data has been lost in transit from source to destination, TCP will retransmit the data until either a timeout condition is reached or successful delivery is achieved. TCP has the capability of detecting duplicate messages and discards them appropriately. TCP has a window-based flow control mechanism built in to regulate the data flow from source to destination. If the sending node is transmitting too fast for the receiving node, the flow control mechanism will take effect to slow down the data transfer. In addition to flow control, TCP also has a window-based congestion control mechanism built in to achieve congestion avoidance. When TCP detects any packet loss, the transmission window will be reduced to relieve the congestion along the path. Both flow control and congestion control make TCP very robust in different network environments.

IP

IP is the primary layer 3 protocol in the Internet suite. The main function of IP layer is to route packets in different network segments. In addition, IP provides fragmentation and reassembly of datagrams (that is, information units) for transmission over networks with different maximum transmission unit (MTU) sizes. IP represents the heart of the Internet protocol suite.

IP Addressing

IP address is a globally unique, 32-bit number assigned by the network information center and network administrator. Globally unique addresses permit IP networks anywhere in the world to communicate with each other. By convention, each byte in a 4-byte IP address is expressed as a decimal number (0 to 255) and separated with a period. For example, the IP address of my machine is 192.168.1.36.

An IP address is divided into two parts. The first part designates the network address; and the second part designates the host address. IP addressing supports three different network classes. Class A networks allocate 8 bits for the network address field and are intended mainly for use with a few very large networks. Class B networks allocate 16 bits and are intended for use with large networks. Class C networks allocate 24 bits for the network address field and are intended for use with small networks. Class C networks only provide 8 bits for the host field. Therefore

Figure 10: IP addresses for class A, B, C networks

the number of hosts per class C network may be a limiting factor. In all three cases, the left most bit(s) indicate the network class. Figure 10 shows the address formats for class A, B, and C IP networks.

It is convenient for most class A and class B networks to be internally managed as a much smaller and simpler version of the large network organizations. The two or three bytes available for host address are often divided into a *subnet* number and a workstation ID. Subnets provide extra flexibility for the network administrator. The administrator can subdivide the network into small units. This is done by “borrowing” bits from the host portion of the address and using them as a subnet field, as depicted in Figure 11.

The number of bits that can be borrowed for the subnet address varies. To specify how many bits are used and where they are located in the host field, IP provides subnet masks. Subnet masks use the same format and representation technique as IP addresses. Subnet masks have ones in all bits except those that specify the host field. For example, the subnet mask that specifies 8 bits of sub-netting for class A address 192.0.0.0 is 255.255.0.0. The subnet mask that specifies 16 bits of sub-netting for class A address 192.0.0.0 is 255.255.255.0. Subnet masks can be passed through a network on demand so that new nodes can learn how many bits of sub-netting are being used on the network.

IP Routing

An “internet” is a group of interconnected networks. The Internet is the collection of networks that permits communication between most research institutions,

Figure 11: IP subnet addresses

universities, and many other organizations around the world. Routing in IP networks is organized as a hierarchy structure. Some routers are used to move information through one particular group of networks under the same administrative authority and control. Such an entity is called an autonomous system. Routers used for information exchange within autonomous systems are called interior routers. They use a variety of interior gateway protocols (IGPs) to accomplish the task. Routers that move information between autonomous systems are called exterior routers. They use the exterior gateway protocol (EGP) or border gateway protocol (BGP). More details on hierarchical routings are described in other chapters.

Other Advanced Packet-Switching Networks

Packet-switching networks have experienced tremendous growth and development in recent years. IP network has become the dominating networking technology. Much research and development has been conducted in packet-switching networks. Particularly, advances in IP network routing, QoS managements, active queue management and congestion control, network traffic management, etc. have been made to design an efficient network supporting various applications and services.

In addition to layer 3 (such as IP) network development, the evolution in LAN has also gone through rapid changes. The most important LAN technologies are the fast Ethernet and Gigabit Ethernet, which are the extensions of the classical Ethernet with carrier sense multiple access with collision detection (CSMA/CD) to higher speeds.

Another important packet-switching technology is MPLS, that is, multiprotocol label switching. MPLS is defined by IETF as a base technology for using label switching and for implementation of label-switched paths over various link level technologies, such as frame relay, SONET, ATM, and Ethernet protocols, and so on. MPLS speeds up the traffic flow transmission by setting up a specific path for a given sequence of packets and saving the time needed for a router to route the packet. MPLS allows packets to be forwarded at the layer 2 (switching) level rather than at the layer 3 (routing) level. In addition to speeding up the network traffic, MPLS makes it easy to manage a network for quality of service (QoS). As a result of these reasons, MPLS technique has been rapidly adopted in today’s networks carrying mixed traffic.

More detailed descriptions on Ethernet LAN, MPLS, and other advanced technologies are provided in other chapters.

GLOSSARY

ATM: asynchronous transmission mode. It is an advanced fast packet-switching technique. It provides quality of service for different applications.

Circuit switching: A switching technology used in conventional telephone networks. A dedicated circuit or connect is pre-allocated for an entire call.

Frame relay: An enhancement of X.25 for packet switching. It switches packets fast via eliminating the error checking procedures at the network nodes.

IP: Internet protocol.

ITU-T: International Telecommunication Union Telecommunication Sector. It is an international standards organization that provides recommendations in telecommunication technologies.

Packet switching: A switching technology used in modern data communication networks. Packets are individually allocated bandwidth dynamically and shared the transmission bandwidth with other users.

TCP: Transport control protocol.

X.25: The first international standards on packet switching. It defines the protocol interfaces between user terminals and the networks to facilitate network interconnection.

INTRODUCTION

The fundamental purpose of a communication system is to exchange information between two or more devices. Such a system can be optimized for voice, data, or both. In its simplest form, a communication system can be established between two *nodes* (or *stations*) that are directly connected by some form of point-to-point transmission medium. A station may be a PC, telephone, fax machine, mainframe, or any other communicating device. This may, however, be impractical, if there are many geographically dispersed nodes or the communication requires dynamic connection between different nodes at various times.

An alternative method to a point-to-point connection is establishing a *communication network*. In a communication network, each communicating device (or station) is connected to a network node. The interconnected nodes are capable of transferring data between stations. Depending on the architecture and techniques used to transfer data, two basic categories of communication networks are *broadcast networks* and *switched networks*.

In broadcast networks, a single node transmits the information to all other nodes and hence, all stations will receive the data. A simple example of such network is a citizens' band (CB) radio system, in which all users tuned to the same channel can communicate with each other. Other examples of broadcast networks are satellite networks and Ethernet-based local area networks, where transmission by any station will propagate through the network and all other stations will receive the information.

In a switched network, the transmitted data is not passed on to the entire medium. Instead, data are transferred from source to destination through a series of intermediate nodes. Such nodes, often called *switching nodes*, are only concerned about how to move the data from one node to another until the data reaches its destination node. Switched communication networks can be categorized into different types such as the following:

- Circuit-switched networks.
- Packet-switched networks.

- Message-switched networks.
- Burst-switched networks.

In this chapter we focus on circuit-switched networks. In a circuit-switched network, also called line-switched network, a dedicated physical communication path is established between two stations through the switching nodes in the network. Hence, the end-to-end path from source to destination is a connected sequence of physical links between nodes and at each switching node the incoming data is switched to the appropriate outgoing link.

A circuit-switched communication system involves three phases: circuit establishment (setting up dedicated links between the source and destination); data transfer (transmitting the data between the source and destination); and circuit disconnect (removing the dedicated links). In circuit switching the connection path is established before data transmission begins. Therefore, the channel capacity must be reserved between the source and destination throughout the network and each node must have available internal switching capacity to handle the requested connection. Clearly, the switching nodes must have the intelligence to make proper allocations and to establish a route through the network.

The most common example of a circuit-switched network can be found in public telephone network (PTN) supporting services such as POTS (plain old telephone systems) and long-distance calls. Other examples of circuit-switched services are integrated services digital network (ISDN), and switched 56, 64, and 384 (Kbps) services. The majority of wireless application protocols (WAP)-enabled phones also operate on top of circuit-switched networks. Furthermore, many public networks dedicated to data transport also use circuit-switching techniques; an example of a network in Europe is circuit-switched public data network (CSPDN), which transports data on circuit-switched networks using the X.21 protocol. Circuit switching also has wide applications in optical networks including wavelength division multiplexed (WDM) systems and WDM SONET networks.

With tremendous growth in data communications and Internet traffic in the past few decades, circuit-switching technology may appear to have lost its importance and in fact, many believe that it will eventually be replaced by more residual competitors such as packet switching. Many major telephone companies have considered spending billions of dollars to upgrade their switches to support packet switching. However, the existing \$100 billion investment in the public telephone network in the United States makes such migration non-trivial. In fact, there seems to be a renewed interest in implementing circuit switching in optical networks as a result of the ease of building very high-capacity optical circuit switches and rapid reconfiguration around failure. For example, many researchers have proposed using circuit switching instead of or in addition to packet switching at the core of the Internet where packet switching offers low link utilization.

In the remainder of this chapter we first examine the basic concepts of circuit switching networks and various switching technologies. Then, we look at different circuit-switched services. We briefly describe the general architecture of circuit-switched optical networks. We also investigate the performance of circuit-switched networks. Finally, we look at the future of circuit-switching technology and its position in future applications.

CIRCUIT-SWITCHED NETWORKS

In this section we describe the elements of a circuit-switched network and examine their basic functionalities. Figure 1 shows a circuit-switched network. Three basic elements in this network are end-stations (or terminals), transmission media, and switching nodes. Through one or more switching nodes, end-stations can be temporarily interconnected to each other. A switching node can simply provide a transmission path between other switches and it may not be connected to any terminals; this is the case with Node C in Figure 1. In general, switching nodes in circuit-switched networks are the most invisible elements to the users and yet represent the most important elements in terms of offering available services.

Depending on the transmission technology and the physical transmission media over which connections take place, a switching node can be based on electrical (analog or digital) or optical technology. In the following paragraphs we first describe the main building blocks of a generic switching node and then examine various switching technologies.

Switching Node Architecture

In general, a switching node provides the following basic functionalities:

- signaling
- control
- switching
- interfacing

The basic function of the signaling element in a switching node is to monitor the activity of the incoming lines and to forward appropriate status or control information to the control element of the switch. Signaling is also used to place control signals onto outgoing lines under the direction of the control element. The control element processes incoming signaling information and sets up connections accordingly. The switching function itself is provided by a switching matrix (or fabric), which is an array of selectable cross-points used to complete connections between input lines and output lines, as shown in Figure 2a. The switching fabric can operate in the electrical or optical domain. The network interface provides the hardware required to connect different devices, such as analog, digital TDM lines, optical fibers, etc. to the switch matrix. These basic components of a switching node are depicted in Figure 2b.

An important characteristic of a circuit-based switch is whether it is blocking or non-blocking (Stallings, 1999). Blocking occurs when the switching matrix does not allow some input lines to be connected to output lines. Consequently, at the network level, some stations will not be able to be connected together. A non-blocking switching node, on the other hand, allows all inputs to be connected

Figure 1: A circuit-switched network

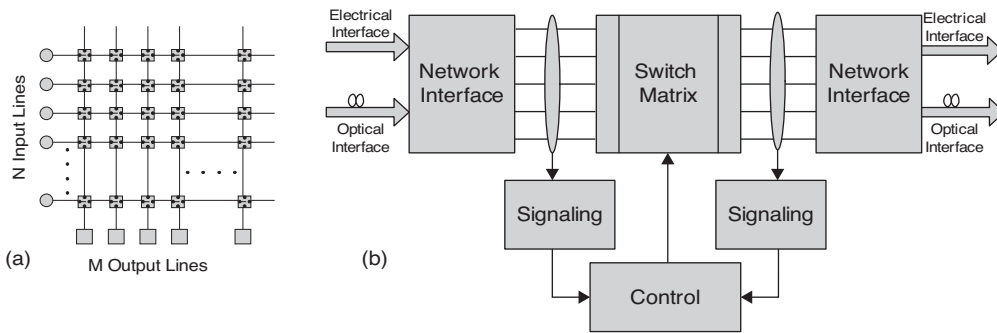

Figure 2: (a) An array of selectable cross-points, (b) switching node elements

to all outputs. As a result, a network with non-blocking switching nodes permits all stations to be connected (in pairs) at once and grants all possible connection requests as long as the destination node is free. Hence, it is desirable to have a non-blocking configuration, particularly in data communications. However, a major consideration is the high cost of non-blocking switching nodes. In fact, in many cases it is more practical to build blocking switches where the blocking probability is acceptable.

The switching function between the inputs and outputs in the matrix can be based on one or more of the following switching technologies:

- space-division
- time-division
- frequency-division
- wavelength-division

In the following sub-sections we briefly describe the characteristics of each switching technology.

Space-Division Switching

In space-division switching each input takes a different physical path in the switch matrix depending on the output. Hence, when a connection is established through a space switch matrix, a permanent physical contact is made on the matrix of cross-points. The connection will be maintained throughout the call duration. This technology can be primarily developed to accommodate analog transmission. Broadly speaking, space-division switching can be classified into three types: manual, electro-mechanical, and stored-program control.

Historically, circuit switching was designed for making standard telephone calls on the public telephone network. Hence, development of switching technology is traced back to the first commercial manual telephone switchboard used for public telephone network (the first manual switching machine started operating on January 2, 1878, in New Haven Connecticut, two years after the invention of the telephone, and it was only capable of supporting 21 subscribers (Bellamy, 2000). Every subscriber's line was terminated on the rear of the switchboard, while the front of the switchboard consisted of many loop jacks. Upon requesting a connection, the operator would manually connect the appropriate jacks using a loop cord with a loop plug on each end.

The second generation of space-division switching systems was electro-mechanical. Two common types of such systems were *step-by-step* (also known as the Strowger switch in honor of its inventor) and *crossbar* switches. Other types of electro-mechanical switches were All Relay, Panel, and X-Y systems; however, they were not as widely used.

A basic step-by-step switch has a single input terminal and multiple output terminals. Connection from the input terminal to the outputs is controlled by an internal rotary contact, or wiper. As the wiper rotates, it establishes a contact between the input and output terminals. Each time the user dials a rotary-dial digit, the rotary contact is advanced one position, and connects the input terminal to the next output terminal. This process continues until all digits are dialed (Chapuis, 1982; Clark, 1997). The principle of a step-by-step switch with a single input terminal and multiple output terminals is shown in Figure 3.

Figure 3: A step-by-step switch with a single input terminal and multiple output terminals

Figure 4: A crossbar switch with four incoming circuits, 4 outgoing circuits, and 16 switch cross-points

In a crossbar switch (also known as cross-point switch) as digits are dialed, the control element of the switch receives the entire address before processing it. The cross-points of the crossbar switch are mechanical contacts with magnets to setup and hold a connection. The term crossbar arises from the use of crossing horizontal and vertical bars to initially select the contacts on the cross-point. Once the circuit is established, the switching contacts are held by electromagnets energized with direct current passing through the established circuit. When the circuit is opened, the loss of current causes the cross-points to be released.

Figure 4 shows a crossbar switch with four incoming circuits, four outgoing circuits, and 16 switch cross-points, which may be active or inactive. Any of the incoming circuits can be interconnected to any one, and only one, of the outgoing circuits. The figure shows the simultaneous interconnections between the following circuits: A to 2, C to 1, D to 4, and B to 3. A typical internal design of the switch cross-point is also depicted in Figure 4.

Step-by-step and crossbar switching systems use electro-mechanical components for both switching matrix and control elements. In 1965, Bell Systems introduced the first computer-controlled switching system, known as No. 1 ESS (Electronics Switching System), which was used in the public telephone network (Martin, 1985). The electronic switching capability of No. 1 ESS was primarily referred to as the computer-controlled switching and not the nature of the switching matrix itself. In fact, the switching matrix was still using electro-mechanical reed relays (nickel-iron reeds sealed in a glass tube, which make contact as a result of magnetic field induced by coil around them). These switches were considered as

the first stored-program control switch types used in the public telephone network.

Time-Division Switching

With the advents of digital technology and the development of pulse code modulation (PCM) both voice and data could be transmitted via digital signals. Digital technology led to a fundamental change in the design and architecture of switching systems. The need for time-division switching arises from the fact that digital signals are often carrying multiple individual circuits, or channels, in appropriate *timeslots* (TS). In such systems, when two different multiplexed channels are interconnected together through the switch matrix a *virtual circuit* is established. This is done by interchanging timeslots, each of which maintain partial contents of a particular channel. This operation is referred to as timeslot interchanging (TSI) (Stallings, 1999).

In a digital switch architecture, an incoming channel must be connected to a channel on any outgoing stream. A common architecture to achieve this utilizes both time-division switch capability, to shift channels between timeslots, and space-division switching capability, to enable a different physical outgoing line system to be selected. This architecture is referred to as time-space-time (TST).

Figure 5 shows a multistage time-space-time architecture to switch the timeslots of two digital line systems, each containing 24 time slots. The incoming signals are directly fed into the time switch, the output of which feeds the space switch in the middle. The output of the space switch feeds another time switch to which the outgoing

Figure 5: A time-space-time switch architecture, connecting channel 1 and 2 on incoming stream A to channel 24 on outgoing streams B and A, respectively

signals are connected. This figure shows timeslots (channels) 1 and 2 in incoming port (stream A) are switched to timeslot (channel) 24 in the outgoing stream B and A, respectively. Note that the second time switch stage is necessary to ensure that multiple timeslots in one incoming stream are not superimposed or blocked. Having more stages can further improve the switch performance. In addition to TST, some of the more common structures used in commercially available systems are TSSST, STS, SSTSS, TSTST.

The first time-division switching system deployed in the United States was the AT&T-designed No. 4 ESS, which was placed into service in 1976. The No. 4 ESS was considered as the first truly digital high-capacity switch adopted in the public telephone network. It implemented digital electronics in its control unit and switching matrix and was capable of serving a maximum of 53,760 circuits. Later, AT&T introduced No. 5 ESS, an improved version, handling 100,000 lines.

Frequency and Wavelength-Division Switching

Prior to full development of digital technology, telephone networks used frequency-division multiplexing (FDM) to carry several voice channels on a single physical circuit (e.g., a twisted cable). In these systems, multiple voice channels would be modulated onto carriers separated by some frequency spacing (e.g., 4 kHz). The composite signal, occupying the frequency range 60 to 108 kHz, was known as a group. In turn, five groups could themselves be multiplexed by a similar method into a super-group, containing 60 voice channels. Advances in FDM, allowed even higher levels of multiplexing, supporting transmission of hundreds of voice channels down a single connection.

Today, with the advances in optical networks, the same basic multiplexing principles used in FDM systems are being employed to optical signals. This is known as wavelength-division multiplexing (WDM). In fact, WDM

is an analog multiplexing technique where the original signals are frequency shifted to occupy different portions of frequency spectrum of the transmission media. With the emergence of dense WDM (DWDM) system, 64 to 160 wavelengths (or channels) can be densely packed at 50 or 25 GHz intervals. Hence, the frequency and wavelength-division switching, in practice, are very similar. In the remainder of this section, we consider wavelength-division switching architecture (Toba, 1986).

WDM optical networks consist of optical switches, which are interconnected using WDM transmission systems. The basic functionality of the optical switch is to ensure that the data carried on any wavelength channel on any incoming optical link can be directed to any wavelength on any outgoing optical link. Based on the switching fabric technology, optical switches can be classified into two categories: *opaque* and *transparent* optical switches. An opaque optical switch, also called *optical cross-connect* (OXC), first, converts incoming optical signals to electrical signals, then, switches the electrical signals using an electronic switching fabric, and finally, converts the electrical signals back to optical signals at the output (Bernstein, 2003). A major disadvantage of such systems is that they need to perform multiple opto-electrical translations that can be both complex and expensive.

A transparent optical switch, also called *photonic cross-connect* (PXC), on the other hand, does not require any opto-electrical translation and switches incoming signals in optical domain. The photonic switch fabric can be developed using a variety of technologies, including opto-mechanical, electro-optic, acousto-optic, thermal, micro-mechanical, liquid crystal, and semiconductor switch technologies. In practice, these technologies differ based on their performance characteristics such as switching speed, power loss as optical signals are switched, and wavelength independency in which switching is independent of the specific wavelength being switched. Figure 6 depicts a typical multistage photonic switch equipped with wavelength converters.

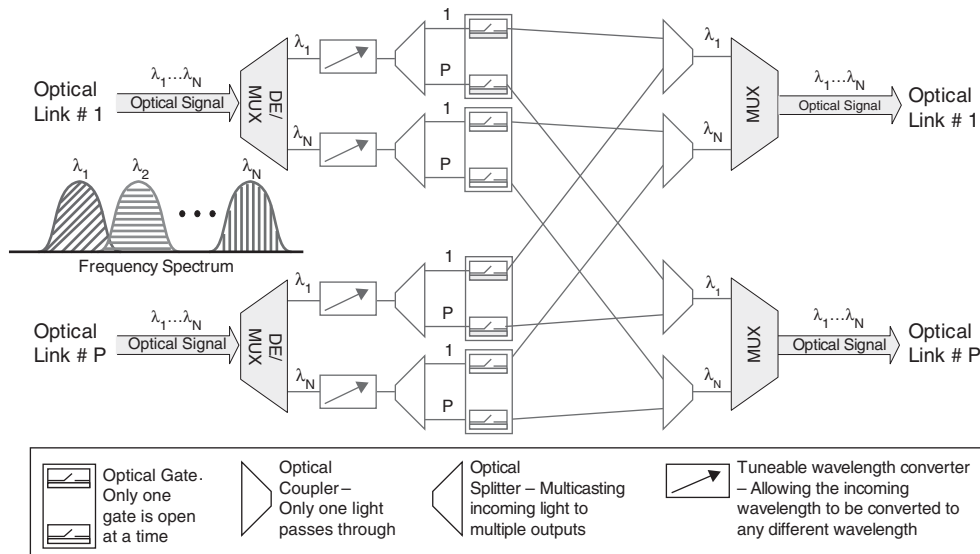

Figure 6: A typical optical switch architecture with wavelength converters, capable of supporting P incoming and outgoing optical links, each having N wavelength channels

Note that in this architecture, the photonic switch fabric is a matrix of optical gates. Similar architectures have been proposed and developed to eliminate the need for costly wavelength converters. With the current technology, control mechanism in the photonic switch fabrics is performed electronically.

Circuit-Switching Advantages and Disadvantages

Circuit switching was the dominant switching technology for more than 100 years. With such a long technological history, circuit switching is well understood, extremely well developed, and widely deployed in the form of the worldwide public telephone system. Furthermore, advances in solid-state technology and micro-processors have led to constant improvement of capabilities of circuit-switching technology and, consequently, its cost effectiveness. In addition, new switching techniques, including wavelength-division switching, as well as high-speed signaling between switches, such as *common channel signaling* (CCS), have reduced average circuit setup delay and provided numerous new features.

In spite of emergence of newer switching technologies, namely packet switching, circuit-switching technology remains an appropriate and easily used technique with many unique advantages. One of the major advantages of circuit switching is that it is an essentially transparent service with no storage requirement. Once the connection is established, constant-rate data is provided to the connected stations. An important consequence of transparency is that no buffer overhead is required to accommodate data bursts that can be created by store-and-forward packet switching. Furthermore, the analog or digital data is passed through as-is from source to destination. Clearly, upon establishing the switched path, the time delay in delivering the data is only that resulting from speed-of-light delays, which are typically small compared to buffer delays, allowing real-time interaction between stations.

Circuit-switching technology also has major drawbacks, which make it less desirable for certain applications. A major issue with circuit switching is that all

resources must be available and dedicated through the network between terminals before the communication takes place. Otherwise, the communication request will be blocked. This can result in potential channel inefficiency. For example, consider a case in which channel capacity is dedicated for the entire duration of a connection, however, no data is actually being transferred. For voice communications, since the idle times are minimum, high utilization can be expected. However, for data communications, since the capacity may be idle during most of the time of the connection (e.g., when we are only reading a downloaded Web page), circuit switching can result in relatively low utilization.

Another major issue with circuit switching is that in order to setup circuits between end-stations, circuit-switching facilities must be capable of processing large signaling at high-speed. Hence, existing systems may not be efficient for *bursty* traffic with short message durations and sporadic transmissions.

CIRCUIT-SWITCHING SERVICES

Today, the public telephone network remains, by far, the largest circuit-switched network in the world. As more data communication applications and services are emerged, it becomes critical to develop a technology that creates general integrated voice and data network that can be available to all users. This led to the development of integrated services digital networks (ISDN). In the remaining of this section we briefly describe examples of circuit-switched services as listed in Table 1.

Plain Old Telephone Service (POTS)

Prior to the existence of new types of networks, all communication systems had to be built based on the existing telecommunications facilities, which were largely oriented to what the common carriers refer to as plain old telephone service, known as POTS. The original POTS telephone network was designed and implemented to transfer analog voice signals. Consequently, even today, in order to use POTS for data communications, it is necessary to use a modem to convert the data to a form

Table 1: Examples of Circuit-Switched Services

Type of service	Bandwidth	Features
POTS	<64 Kbps	Adequate for transmitting text and low quality video; it is a dial-up connection requiring modem; limited by 3 to 4 KHz bandwidth.
Switched 56	64 Kbps	Dial-up connection requiring DSU/CSU; sufficient for low-resolution video; also used as backup facilities.
Leased Lines	64 Kbps to 274 Mbps	Dedicated lines; expensive but dependable and offer high-quality connection. Typically, they are provisioned within the circuit-switched infrastructure for the duration of a lease.
ISDN	144 Kbps to 2 Mbps	End-to-end digital connectivity with different interfaces offering various bandwidths.
SONET	$N \times 51.84$ Mbps	Used with optical fibers; $N = 1, 3, 12, 48, 192, 768$

suitable for voice-transmission media. Modem standards have been developed by ITU, formerly known as CCITT (*Comité Consultatif International Téléphonique et Télégraphique*), in the V-series Recommendations. Common examples of modem standards are V.32 (4.8 Kbps), V.34 (28.8 Kbps), V.42 (38.4 Kbps), and V.90 (56 Kbps).

The data transmission rate that can be obtained over a POTS connection is typically less than 64 Kbps. These rates are adequate for text and audio transmission. However, they are not sufficient for good quality video transmission in real-time. Video applications, such as video telephones, that operate over POTS often use small picture sizes in conjunction with image compression.

Switched 56 Service

Switched 56 service is a dial-up digital service provided by local and long distance telephone companies. For a connection, a data service unit/data channel unit (DSU/CSU) is used instead of a modem. Switched 56 service uses a 64 Kbps channel, but one bit per byte is used for band signaling, leaving 56 Kbps for data. This service allows the transmission of information over one or two twisted cable pairs to multiple points at a data rate of 56 Kbps. Switched 56 service is ideally suited for use as a backup facility to leased lines where, if a break is detected in the leased line service, the data service unit (DSU) will automatically re-establish a connection using the switched 56 dial-up facility. This service is most cost-efficient for individuals and businesses that require moderate-volume file transfers, but do not need to have a permanent connection to all their locations.

Leased Lines

A leased line is a dedicated communication line that an individual or business can own and does not share with any other users. As a result, leased lines are highly dependable and offer high-quality connections. Leased lines are excellent for providing required quality of service (QoS) for the transmission of delay and bandwidth-sensitive applications such as multimedia information (Sharda, 1999). However, the main disadvantage of leased lines is the high cost. Leased lines can be analog or digital.

Analog Leased Lines

This type of access is often used for network usage with full-time connectivity requirement. An analog leased line does not require any dial-up procedure. In addition, it provides higher quality connection and higher signal-to-noise ratio, leading to higher data transmission rate as compared to those on dial-up lines.

Digital Leased Lines

The digital leased line access is often used for large networks serving many users and requiring a high level of reliability. The digital leased lines offer various bandwidths. Common examples of digital leased lines in the United States, Japan, and Korea are fractional T1 (FT1), T1, T2, T3, and T4. T1 is a dedicated connection supporting data rates of 1.544 Mbps. A T1 digital line consists of 24 individual channels, each of which supports 64 Kbps. Each

Table 2: Various Digital Leased Lines and Their Bandwidths

Line type	Bandwidth	Application
Switched 384	384 Kbps	High-quality video conferencing
T1	1.544 Mbps	Compressed video
T2	6.312 Mbps	Broadcast TV quality compressed video
T3	44.70 Mbps	HDVT-quality video transmission
T4	274.0 Mbps	Multiple video channels

64-Kbps channel, referred to as DS0, can be configured to carry voice or data traffic. The framing specification used in transmitting digital signals in Europe is called E1, which operates at 2.108 Mbps and contains 32 DS0 channels. Other levels of digital transmission are T2, T3, etc., which allow digital transmission at higher line rates.

In addition to the above rates, many telephone companies offer fractions of individual channels available in a standard T1 line, known as fractional T1 access. Bit rates offered by a fractional leased line can be 64 Kbps (one channel), 128 Kbps (2 channels), 256 Kbps (4 channels), 384 Kbps (6 channels), 512 Kbps (8 channels), and 768 Kbps (12 channels), with 384 Kbps (1/4 T1), and 768 Kbps (1/2 T1), also known as Switched 384 service and Switched 768 service, being the most common. Switched 384 service is particularly common for supporting high volumes of data and multimedia applications. Table 2 lists various digital leased lines along with their bandwidth and common multimedia applications.

Integrated Services Digital Network (ISDN)

The ISDN was designed in the 1980s to offer end-to-end digital connectivity, while providing the required QoS with data rates in the range of Kbps to Mbps over switched connections. ISDN also offers a more economical alternative to digital leased lines. In order to provide even higher data rates, the original ISDN was extended to broadband ISDN (BISDN) (Martin, 1985).

The ISDN services are provided to users as ISDN interfaces, each comprising a number of ISDN channels. Using 64-Kbps channels, called bearer or B channels, ISDN provides access to the digital network. ISDN provides lower error rate compared to typical voiceband modems and a relatively high bandwidth data channel. On the other hand, ISDN uses 16-Kbps or 64-Kbps signaling D channels to access the signaling network, which allows features such as accessing packet switching network, user-to-user message transfer, and simultaneous signal processing while having active connections. A very attractive application of signal accessing is to provide end-users the flexibility to dynamically reconfigure virtual private networks within the public network and have them interoperate with private facilities without a loss

Table 3: ISDN Interfaces

Interface type	Channels	Bandwidth	Application
Basic-rate interface	2B + D	144–192 Kbps	Digital voice and data
Primary-rate interface	23B + D or 30B + D	1.544 or 2.048 Mbps	Multimedia and LAN to LAN connection
Hybrid interface	A + C	Analog voice and 16 Kbps data	Hybrid connection for transition period

of features. Other ISDN channels are A and C, providing access to POTS and low-speed digital data transmission, respectively.

ISDN channels (A, B, C, D) are combined to provide standard interfaces: basic rate interface (BRI), primary rate interface (PRI), and hybrid interface. Table 3 lists these interfaces with their channels and common applications.

Basic Rate Interface (BRI): Basic rate access provides two clear 64-Kbps information channels and one 16-Kbps signaling channel (2B + D), given the total information rate of 144 Kbps. Each of the B channels can be used independently of the other, supporting simultaneous voice and digital data communications.

Primary Rate Interface (PRI): Primary rate interface gives an information transfer capability of 1.544 Mbps. The bandwidth can be configured in a variety of ways including having 23 B channels plus one D channel to connect a number of devices to an ISDN network via, for example, a PBX. PRI in Europe is available as a 2.048-Mbps connection with 30 B channels and one D channel.

Hybrid Interface: The hybrid interface allows connections that use a hybrid of analog and digital communications. This interface has been included in the ISDN systems to provide a transition path from the old POTS service to digital services.

Synchronous Optical Network (SONET)

The synchronous optical network (SONET) is a multiplexing system similar to conventional time-division multiplexing. However, SONET was developed to be used with optical fibers. SONET systems are common examples of optical circuit-switched networks, which offer high-speed communications (we will discuss these networks in the next section). The lowest level of SONET hierarchy is the basic SONET signal referred to as the synchronous transport signal level-1 (STS-1). STS-1 has a 51.84 Mbps synchronous frame structure compromised of 28 DS-1 signals. Each DS-1 signal is equivalent to a single 24-channel T1 digital line. Thus, one STS-1 system can carry 672 individual 64-Kbps voice or data channels (24x28). With STS-1, it is possible to extract or add individual DS-1 signals without completely disassembling the entire frame.

Higher level signals are referred to as STS-N signals. An STS-N signal is composed of N byte-interleaved STS-1 signals. The optical counterpart of each STS-N signal is an optical carrier level-N signal (OC-N). Although,

the SONET specification is primarily concerned with OC-N interconnect standards, electrical signals within the SONET hierarchy are used for interconnecting network elements operating at lower rates. Common values of N are 1, 3, 12, 48, 192, and 768. An interesting feature of SONET frames is that they have constant period. That is, an OC-3 (155 Mbps) frame has the same 125 microsecond period as an OC-768 (40 Gbps) frame, although the OC-768 frame carries a much larger payload. This period corresponds to the 8-KHz sampling period (and clock rate) of the first PCM-based quasi-digital networks.

OPTICAL CIRCUIT SWITCHING

In early generations of circuit switching, circuits were established over copper wires and traversed a number of electronic circuit switching nodes. As the demand for network bandwidth increased, copper wire was (and continues to be) replaced by optical fiber, which provides significantly more bandwidth. The bandwidth of optical fiber can be further exploited through the use of WDM technology.

An optical circuit-switching network is similar to the example shown in Figure 1. In an optical network, however, transmission media are WDM links and switching nodes are optical (opaque or transparent). Using WDM transmission technology, the optical transmission spectrum is carved up into a number of overlapping wavelength bands. Each wavelength band can support a single communication channel operating at the peak electronic rate. Today, the majority of optical networks deployed in long-distance telecommunication networks are point-to-point DWDM SONET networks, where each node requires optical-electronic-optical (O-E-O) conversions and electronic switching.

As we mentioned before, in an optical network that utilizes photonic cross-connects (PXC), all circuits over the network are established in the optical domain. End-to-end all-optical circuits offering bandwidth equivalent to the bandwidth provided by a single wavelength, are referred to as *lightpaths*. Such optical networks are called *wavelength-routed* WDM networks (Mukherjee, 2006; Ramaswami, 2001). If wavelengths cannot be converted from one wavelength to another at PXC, then the same wavelength must be used on all links of a lightpath. This requirement is known as the *wavelength continuity constraint*. Figure 7 shows a wavelength-routed network with three lightpaths established. Lightpaths cannot share the same wavelength on the same link. Hence, the lightpath between source 1 and destination 1 and the lightpath

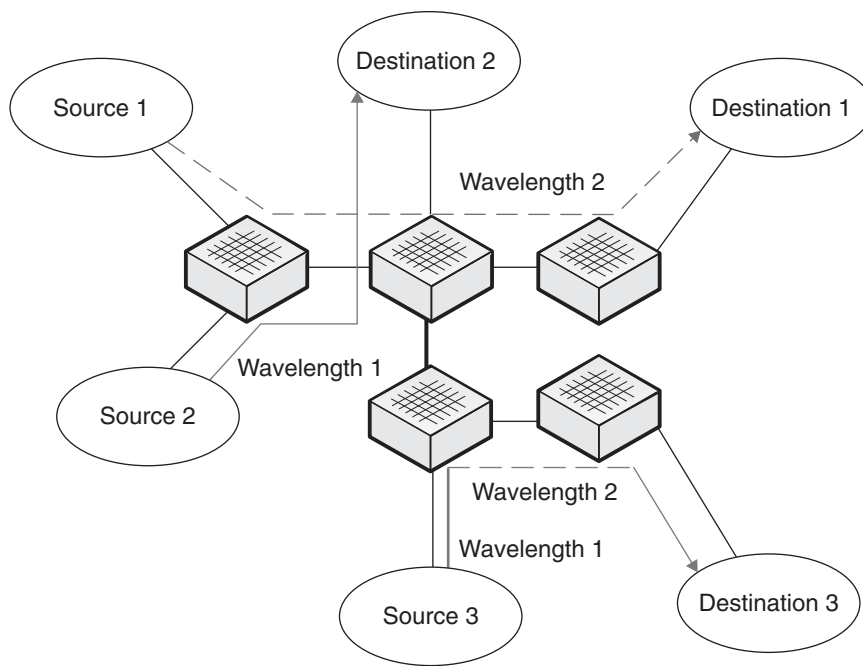

Figure 7: Wavelength-routed WDM network

between source 2 and destination 2 use different wavelengths. The lightpath between source destination 3 utilizes two different wavelengths without wavelength continuity constraint. This can be achieved using wavelength converters at intermediate nodes.

A key challenge in the practical implementation of optical networks is to develop efficient algorithms and protocols for establishing lightpaths (Zang, 2001). Such algorithms must select routes and assign wavelengths to all-optical circuits in a manner that efficiently utilizes network resources. Furthermore, signaling protocols must set up a lightpath in a timely manner, and must properly distribute control messages and network state information. In emerging optical networks, signaling and control for connection establishment may be implemented by one of three methods. First, it may be done within the generalized multiprotocol label switching (GMPLS) framework. GMPLS defines the control architecture for establishing circuits, is based on MPLS in IP networks, and is primarily a construct supported by router vendors. A second approach uses the ASON ITU standards and has been put forward primarily within the carrier and telecom community. Finally, some research networks support a centralized control scheme that allows advanced reservation and scheduling of dedicated bandwidth.

CIRCUIT-SWITCHED NETWORK PERFORMANCE

When circuits are established, such as establishment of a phone call or a lightpath in a WDM network, the primary performance metrics of interest in circuit-switched networks are delay and blocking. Delay, or connection set-up time, refers to the time required to establish the circuit. Blocking occurs when there are insufficient resources along a given route to support an incoming circuit request. Blocking is often measured in terms of the blocking

probability, which is the probability that an incoming call will be rejected due to the lack of resources.

Delay Analysis

Figure 8 depicts the transmission of data (a message) across four nodes in a circuit-switched network. The primary components of delay in circuit switching are the propagation delay of the signaling message on each link (D_p), the processing delay of the signaling message at each node (D_n), and the transmission delay of data traffic (D_t); for example it takes 0.1 second to transmit a 10,000 bit message onto a 100 Kbps line.

As shown in the figure, before the data (or message) is sent, a certain amount of elapsed time is required to setup the path. First, a setup message is sent through the network to setup a connection to the destination. Processing delay is the time spent at each node setting up the route of the connection.

Once the destination receives the call request, assuming the destination is not busy, it will return an acceptance message. On the return path, no processing delay at intermediate nodes will be required since the connections are already set up. This operation is referred to as *forward reservation*. In *reverse reservation*, however, the setup message will be directly sent to the destination and resource reservation at intermediate nodes occurs as the acceptance message is received; this is to avoid any resource reservation before ensuring that the end-to-end path is available. After the connection is set up, the message is sent as a single block, and the delay at the switching nodes will be negligible. Eventually, following the completion of data transmission, a release message will be sent requesting removal of all connections along the path.

Figure 8 also shows a case where an intermediate node (SW A) rejects a connection request. Note that in this case there is no need to propagate the setup message further to downstream nodes.

Figure 8: Event timing diagram in circuit-switched networks

The total delay prior to transmission of data, as shown in Figure 8, will be $h(2D_p + D_n) + D_n$, where h is the number of hops on the end-to-end path; in our example $h = 3$. This delay is referred to as circuit setup delay. If data transmission delay (D_t) is smaller or equal to the setup delay, circuit switching will not be efficient and it results in low utilization. However, if D_t is much larger than the setup delay, then circuit switching can offer high utilization.

Blocking Probability Analysis

In traditional telephony applications, blocking probability can be analyzed by using standard queuing theory techniques. The simplest model is one in which we evaluate a single link in the network and assume that the call arrival rate is Poisson and the call-holding time is exponentially distributed. The assumptions of Poisson arrivals and exponential holding times are standard in the analysis of telecommunications systems and have been found to accurately model the behavior of voice calls.

More complicated blocking models have been developed by evaluating the blocking probability along the entire path of a call rather than on a single link. In such models, there is some degree of statistical dependence among links in the network. It is often sufficient and much simpler to assume that the links along an end-to-end path

are statistically independent of one another. The limitation of such an assumption is a less accurate estimation of the blocking probability.

Single Link Blocking Model

When analyzing the call blocking probability on a single communication link (e.g., the link between SW A and SW B in Figure 8), we assume that the link is capable of supporting C connections, simultaneously (in the case of WDM networks, C can be the number of wavelengths supported by each optical link). Furthermore, we assume that calls arrive (or lightpath requests) according to a Poisson process with rate λ calls per second, and the call holding time (or lightpath duration) is exponentially distributed with an average holding time of $1/\mu$ seconds. Calls are assumed to be independent of each other. Under these assumptions, the link may be modeled as an $M/M/C/C$ queuing system (Schwartz, 1986) and the probability that there are n calls in progress is given by:

$$p(n) = \frac{\frac{1}{n!} \left(\frac{\lambda}{\mu} \right)^n}{\sum_{k=0}^C \left(\frac{1}{k!} \left(\frac{\lambda}{\mu} \right)^k \right)}.$$

An arriving request will be blocked if there are already C calls in progress. Thus, the probability that a call is blocked on the link is given by:

$$p(C) = \frac{\frac{1}{C!} \left(\frac{\lambda}{\mu} \right)^C}{\sum_{k=0}^C \left(\frac{1}{k!} \left(\frac{\lambda}{\mu} \right)^k \right)}.$$

This equation is referred to as the *Erlang B* formula.

Path Blocking Model

In addition to calculating the blocking probability on a given link, it is also possible to estimate the blocking probability of a given end-to-end connection request for a call traversing multiple links (e.g., the path from source to destination in Figure 8, passing through three links). One approach is to model each link in a path as an $M/M/C$ system. We define the arrival rate of connection requests from source node s to destination node d as λ^{sd} calls per second, the arrival rate of connections on link (i, j) as λ_{ij} calls per second, and the route taken by a connection from s to d as $R(s, d)$.

The offered load on a given link, λ_{ij} , can be calculated by adding the traffic from all source-destination pairs that route traffic over link (i, j) :

$$\lambda_{ij} = \sum_{s,d:(i,j) \in R(s,d)} \lambda^{sd}.$$

To simplify the analysis, it is assumed that links are independent of one another. Furthermore, we assume call arrivals are Poisson and call holding times are exponentially distributed with an average holding time of $1/\mu$ seconds. In order for a connection request from s to d to succeed, spare capacity must be available on all links along the route. Alternatively, a connection will be blocked if at least one link in the connection's route has no available capacity. The blocking probability of a request from s to d can then be written as:

$$p(s, d) = 1 - \prod_{(i,j) \in R(s,d)} (1 - p_{ij}(C)),$$

in which

$$p_{ij}(C) = \frac{\frac{1}{C!} \left(\frac{\lambda_{ij}}{\mu} \right)^C}{\sum_{k=0}^C \left(\frac{1}{k!} \left(\frac{\lambda_{ij}}{\mu} \right)^k \right)}.$$

We now consider a simple example in which we calculate the path blocking probability. In this example, we assume that an end-to-end connection traverses two links.

The total load on each link is known. Using the single link blocking model, we can obtain the blocking probability on each link, say p_1 and p_2 . Hence the path blocking probability for the connection will be $1 - (1 - p_1)(1 - p_2)$.

In the above analysis, we assumed that a connection request on any one of the C channels of any incoming link can be connected to any channel on any outgoing link. When the switching operation is performed in the electrical domain, such an assumption is rather trivial. However, in optical networks with PXCs, wavelength converters are required to guarantee such an assumption. Additional analytical models have been developed to calculate blocking probability in optical networks when no wavelength conversion is utilized (Barry, 1996).

FUTURE OF CIRCUIT-SWITCHING TECHNOLOGY

The past half century, packet-switching technology has advanced tremendously and turned into a major competitor for circuit switching. In fact, packet switching has become the dominant technology for data networks, including the Internet. Not surprisingly, many telephone companies have been willing to spend billions of dollars to upgrade their networks to support packet switching, potentially phasing out their circuit-switched based equipments.

However, many researchers and engineers have been investigating the implementation of circuit switching technology in wide area networks (WAN) and optical networks. In fact, circuit-switching technology has been considered as the practical approach in deploying future optical WDM networks. This is mainly a result of the fact that development of all-optical packet switching networks still lacks reliable optical buffers and synchronization techniques. Today, with the current technology, circuit switching is seen as a viable solution to establish transparent optical paths (lightpaths) providing large amounts of bandwidth. The key challenge, however, is to ensure circuit switching can be made rapidly adaptive to traffic fluctuation and connection requests. While many issues related to circuit switching and lightpath establishment have been studied in detail, control plane techniques for setting up optical paths are still under active development.

In emerging core networks, applications are expected to have a wider range of QoS requirements than in existing networks. Bandwidth-intensive applications, such as video on demand, video conferencing, scheduled bulk-file transfer, and grid computing are expected to have strict transmission-completion requirements coupled with high bandwidth requirements. Telemedicine has both high bandwidth and extremely tight jitter requirements. For many such applications, best-effort packet-switched networks are incapable of providing the required services. Therefore, circuit switching in core networks (e.g., core of the Internet) may be expected not only to support static logical links for higher-layer packet switched protocols, but also provide resources directly to end users and applications. Hence, performance of the Internet where circuit switching is implemented at the core, the adaptability of

circuit switching to existing Internet protocols, such as TCP/IP, and many other similar open issues require detailed study (Molinero-Fernández, 2003).

Furthermore, many in the telecommunications community strongly favor circuit switching over development of new packet-based services, due to existing huge investments in circuit-switched networks and their readiness. They question the wisdom of focusing on introducing new switching technologies and protocols, and consequently developing new expensive equipments. Instead, they argue that we must gain more in-depth technical knowledge and develop smarter encoding and transmission techniques, which will work just fine with our existing well-functioning circuit-switched networks (Cringely, 2004).

CONCLUSION

In this chapter, we described the basic principles of circuit-switching technology. We discussed the building blocks of circuit-switched networks and examined its characteristics. We looked at advantages and disadvantages of circuit-switched networks and briefly explained its applications in providing different services. We also examined the basic concepts of circuit-based optical networks and described their operations. Future applications of circuit-switching technology were also outlined in this chapter. We examined various view points and research proposals, which emphasize the importance of circuit-switching technology, particularly, in optical networks and core networks.

GLOSSARY

Bell System: This is an informal name given to the U.S. telecommunications company American Telephone & Telegraph Company (AT&T) before AT&T divested its local exchange telephone service operating companies on January 1, 1984.

CCITT: Short for Comité Consultatif International Téléphonique et Télégraphique, an organization based in Geneva, Switzerland, that sets international communications standards. CCITT changed its name to International Telecommunications Union (ITU), the parent organization, on March 1, 1993.

Citizens' Band Radio (CB): In the United States, it is a system of short-distance radio communication between individuals on a selection of 40 channels within the single 27 MHz (11 meter) band. CB does not require a license and unlike amateur radio can be used for commercial communications.

Common Channel Signaling (CCS): An out-of-band signaling method in which one channel of a communications link is used for carrying signaling for establishment and tear down of calls. The remaining channels are used entirely for the transmission of voice or data.

Data Service Unit/Data Channel Unit (DSU/CSU): A digital interface that provides the physical connection to the digital carrier network.

Frequency-Division Multiplexing (FDM): A scheme in which numerous signals are combined for transmission on a single communications line or channel. Each

signal is assigned a different frequency (sub-channel) within the main channel.

Multi Protocol Label Switching (MPLS): A method used to increase the speed of network traffic flow by inserting information about a specific path the packet is taking to reach its destination. Hence, the router is no longer required to lookup the next node address. MPLS is multiprotocol in that it works with IP, ATM, and frame relay communications methods.

Protocol: A formal and pre-agreed set of rules that govern the communications between two or more entities. The protocol determines the meaning of specific values occurring in specific positions in the stream, the type of error checking to be used, the data compression method, how the sender will indicate that it has finished sending a message, and how the receiver will indicate that it has received a message.

Pulse Code Modulation (PCM): A way to convert sound or analog information to binary information (0s and 1s) by taking samples of the sound and recording the resulting number as binary information.

Quality of Service (QoS): It refers to the capability of a network to provide better service to selected network traffic over various technologies. The primary goal of QoS is to provide priority including dedicated bandwidth, controlled jitter and latency (required by some real-time and interactive traffic), and improved loss characteristics.

Time Division Multiplexing (TDM): A scheme in which numerous signals are combined for transmission on a single communications line or channel. Each signal is broken up into many segments, each having very short duration.

Wireless Application Protocol (WAP): A set of communication protocol standards to make accessing online services via handheld wireless devices such as mobile phones, pagers, two-way radios, Smartphones, and communicators.

FURTHER READING

Since the invention of telephone in 1876, circuit switching has been the dominant switching technology. With such long history, volumes of materials have been dedicated to understanding properties of circuit-switching technology, its architecture, and performance. A comprehensive description of circuit switching technology and its properties can be found in Stallings (1999), Bellamy (2000), and Chapuis (1982). Chapuis (1982) and Clark (1997) provide detail descriptions on switching node architecture and various technologies used in circuit switching nodes. Detailed discussions on frequency and wavelength-division multiplexing are provided in Toba (1986).

Various online articles, including Tomasi (2004), Martin (1985), and Telephone (2006), offer valuable information regarding development of public telephone network and POTs. Applications of circuit switching technology pertaining multimedia services are discussed in Sharda (1999). Tomasi (2004) and Martin (1985) offer excellent discussions on ISDN technology.

Abundant materials are available on optical networking, SONET, and WDM systems. Interested readers can refer to Bernstein (2003), Mukherjee (2006), and Ramaswami (2001) for a complete treatment of these topics. Good surveys describing more advanced topics, such as wavelength routing, and impact of wavelength continuity constraints, can be found in Zang (2001), Ramaswami (1995), and Baroni (1997).

A comprehensive treatment of circuit switching performance is provided in Schwartz (1986). Discussion regarding the performance of optical networks can be found in Barry (1996). Finally, interesting discussions regarding possibility of using circuit-switching technology at the core can be found in Molinero-Fernández (2003). Cringely (2004) provides a good argument as to why circuit switching must be maintained as the future switching technology for telephone companies.

INTRODUCTION

A communication network consists of a collection of devices (or nodes) that wish to communicate and interconnect together. The primary objective in any communication network is simply moving information from one source to one or more destination nodes. Based on the techniques used to transfer data, communication networks can be categorized into broadcast and switched networks. In broadcast networks, data transmitted by one node is received by many, sometimes all, of the other nodes. In switched-communication networks, however, the data transferred from source to destination is routed through the switch nodes. The way in which the nodes switch data from one link to another as it is transmitted from source to destination node is referred to as a *switching technique*. Three common switching techniques are circuit switching, packet switching, and message switching.

In circuit switching, the end-users are interconnected using dedicated paths. The most common example of a circuit-switched communications network is the plain old telephone service (POTS) network. One major issue with circuit switching is that it can be rather inefficient, particularly in data communications (Stallings, 2004). This is because in a circuit-switched network the channel capacity is dedicated for the entire duration of a connection, even if no information is being transferred. Furthermore, in a circuit-switched network, the actual time to setup and tear down the path may in fact be longer than the data transfer time between end-users. Refer to “Circuit Switching” for a complete discussion on circuit switching.

In packet switching, data is divided into smaller units, called packets, and then transmitted through the network. The minimum length of the packet is determined by the network and varies from network to network. Packets are transported over the network between nodes. Each intermediate node queues the packet for a brief time while it determines the route the packet should take to reach the next node. For this reason, a packet-switched network is sometimes called *hold-and-forward* network (Tomasi, 2004). Please refer to “Packet Switching” for a complete discussion on packet-switched networks.

Prior to advances in packet switching, message switching was introduced as an effective alternative to circuit switching. In message switching, end-users communicate by sending each other a *message*, which contains the entire data being delivered from the source to destination node. As a message is routed from its source to its destination, each intermediate switch within the network stores the entire message, providing a very reliable service. In fact, when congestion occurs or all network resources are occupied, rather than discarding the traffic, the message-switched network will store and delay the traffic until sufficient resources are available for successful delivery of the message (Davis, 1973). The message storing capability can also lead to reducing the cost of transmission; for example, messages can be delivered at night when transmission costs are typically lower.

Message switching techniques were originally used in data communications. Early examples of message switching applications are paper tape relay systems and telex networks. Electronic mail (e-mail) and voice mail are also examples of message switching systems. Today, message switching is used in many networks, including ad hoc sensor networks, satellite communications networks, and military networks.

Basic Ideas in Message Switching

Message-switched data networks are hop-by-hop systems that support two distinct characteristics: store-and-forward and message delivery.

In a message-switched network, there is no direct connection between the source and destination nodes. In such networks, the intermediary nodes (switches) have the responsibility of conveying the received message from one node to another in the network. Therefore, each intermediary node within the network must store all messages before retransmitting them one at a time as proper resources become available. This characteristic is often referred to as *store-and-forward* (Stallings, 2004). In message-switching systems (also called store-and-forward systems), the responsibility of the message delivery is on the next hop, as the message travels through the path

toward its destination. Hence, to ensure proper delivery, each intermediate switch may maintain a copy of the message until its delivery to the next hop is guaranteed. In case of message broadcasting, multiple copies may be stored for each individual destination node.

The store-and-forward property of message-switched networks is different from *queuing*, in which messages are simply stored until their preceding messages are processed. With store-and-forward capability, a message will only be delivered if the next hop and the link connecting to it are both available. Otherwise, the message is stored indefinitely. For example, consider a mail server that is disconnected from the network and cannot receive the messages directed to it. In this case, the intermediary server must store all messages until the mail server is connected and receives the e-mails. The store-and-forward technology is also different from admission control techniques implemented in packet-switched or circuit-switched networks. Using admission control, the data transmission can temporarily be delayed to avoid overprovisioning the resources. Hence, a message-switched network can also implement an admission control mechanism to reduce network's peak load.

The message delivery in message-switched networks includes wrapping the entire information in a single message and transferring it from the source to the destination node. The message size has no upper bound; although some messages can be as small as a simple database query, others can be very large. For example, messages obtained from a meteorological database center can contain several million bytes of binary data. Practical limitations in storage devices and switches, however, can enforce limits on message length.

Each message must be delivered with a header. The header often contains the message routing information, including the source and destination, priority level, expiration time. Figure 1 shows an example of a message datagram with possible information embedded in the message header.

It is worth mentioning that while a message is being stored at the source or any other intermediary node in the network, it can be bundled or aggregated with other messages going to the next node. This is known as *message interleaving*. One important advantage of message interleaving is that it can reduce the amount of overhead generated in the network, resulting in higher link utilization.

Message-Switching Characteristics

Message switching offers a number of attractive benefits, including efficient usage of network resources, traffic

regulation, and message storage when messages cannot be delivered. However, there are several drawbacks associated with message-switching techniques. For example, since messages are entirely processed and stored indefinitely at each intermediate node, switches require large storage capacity (Davis, 1973).

In general, message-switched networks are relatively slow. This is because all messages must be entirely stored, processed, and retransmitted. This slow switching scheme may lead to poor performance, particularly in wide area networks (WANs). Although, using various scheduling techniques, time critical messages can be given higher transmission priority, it is always possible that a short message falls in line behind a very long one. Consequently, in message switching, messages initiated by different users can expect large delay variance.

Large overall delay and high delay variations make message-switched networks less suitable for real-time and interactive applications, such as voice communications or multimedia games. Instead, message-switched networks are very attractive for supporting applications which can tolerate high delays, yet very little loss. Furthermore, message switching can be an alternative solution for networks where continuous end-to-end connectivity cannot be guaranteed, such as ad hoc sensor networks. A detailed discussion on advantages and disadvantages of message switching compared to circuit switching and packet switching can be found in the subsection Comparison of Message, Packet, and Circuit Switching in this chapter.

MESSAGE-SWITCHED NETWORKS

In this section we first describe different elements of a message-switched network and examine their basic functionalities. Then we focus on store-and-forward switch node architecture and explain its building blocks.

Network Elements

Figure 2 shows a generic message-switched network allowing message transport from one end-user to another. This network consists of transmission links (channels), store-and-forward switch nodes, and end stations (Tomasi, 2004). The transmission links differ depending on the transmission technology and the physical transmission media over which the communications take place. The store-and-forward switch nodes provide end stations with access to transmission links and other switch nodes. They allow data storage and transport of messages from one node to another until they reach their destination

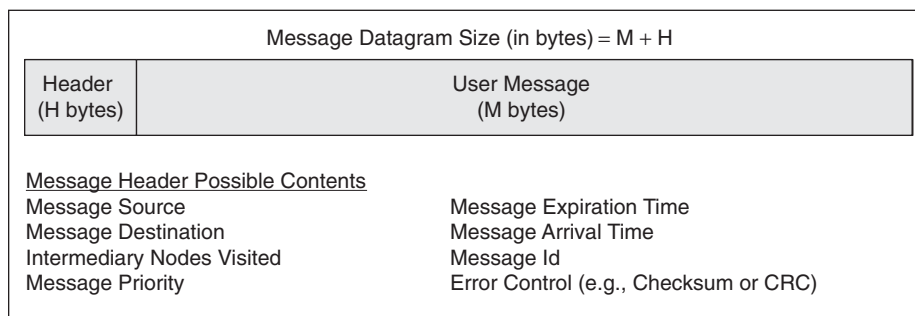

Figure 1: An example of a message datagram structure

Figure 2: A message-switched network

nodes. The end stations can be individual computer terminals, servers, and mainframes. Many networks may be equipped with message gateways, which can convert one message protocol to another.

Store-and-Forward Switches

In general, a switch is a connectivity device that makes forwarding decisions. A store-and-forward switch performs forwarding functionalities similar to a switch in a packet-switched network. However, a store-and-forward switch forwards a message only if sufficient resources are available and the next hop is accepting new data. Hence, the switching strategy in store-and-forward switches is different from the common switching strategy used in packet-switched networks in which the incoming data is forwarded as soon as its destination address is determined.

Figure 3 shows the basic functional blocks of a generic store-and-forward switch node (Shafritz, 1964). In the following paragraphs we briefly outline the basic functionalities of each block.

The message received by a store-and-forward switch is first decoded and queued. When the input processing controller becomes available, it receives the message and analyzes its header for its destination, associated id, and priority level.

The input processing controller can also check for any errors in the message. Upon detection of any errors, it requests message retransmission. Examples of message errors include transmission errors and invalid addressing. Accepted messages with valid headers are stored in storage devices. Any stored message can be accessed or requested for retransmission using a specific id or serial number. After delivery, a copy of the message will be stored for future retransmission. These messages may be retained for many hours, days, or even weeks. The lookup table maintains the forwarding information and keeps track of which messages are waiting for delivery or have already been delivered.

When the output phase begins, the output processing controller retrieves the proper message from the storage device and after assigning a header, passes it to the output buffer queue and line coder block for appropriate formatting and transmission. The output buffer queue can be used to control the message transmission rate.

The output processing controller is also responsible for deciding how to forward the message to the next hop. In general, forwarding decisions used in message-switched networks are similar to routing schemes implemented in packet-switched networks. For example, forwarding decisions can be based on the least congested link, or shortest end-to-end path (Tanenbaum, 2002). A number of routing techniques in packet-switched networks are discussed in "Packet Switching".

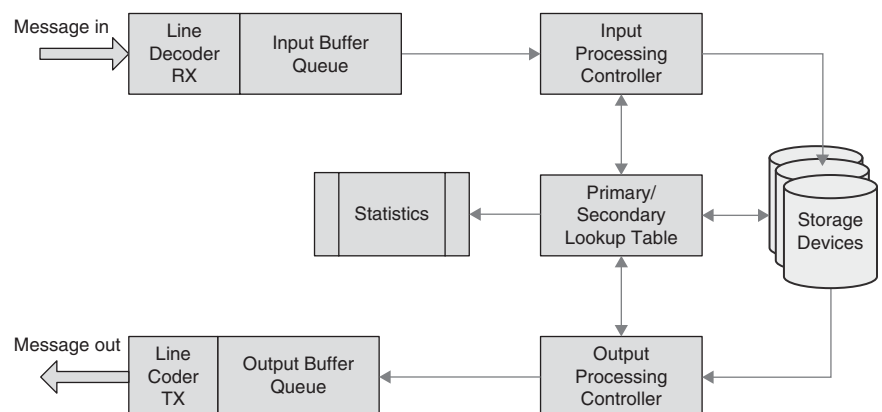

Figure 3: A generic store-and-forward switch node architecture

The exact characteristics of message-switched networks vary depending on features supported by the store-and-forward switch nodes in the network. In the following paragraphs, we elaborate on storage requirements and other features commonly provided by store-and-forward switch nodes.

The storage devices used in a store-and-forward switch node have large storage capacities. This is because messages delivered to each switch are often long and may be stored in the switch indefinitely until sufficient resources are available in order to forward them to the next node. In cases where a message has to be delivered to multiple destination nodes, multiple copies of the messages may be stored for a potentially long duration. A copy of the transmitted message may be stored for possible retransmission until message delivery to the next hop is confirmed. Moreover, the storage capacity must be large enough to avoid any types of data overflow and therefore data loss. The actual storage capacity of the switch is based on the desired performance and can be estimated through statistical analyses. Clearly, as the message arrival rate increases, the amount of data stored in the switch becomes greater, leading to larger storage requirement. Larger storage capacity, on the other hand, leads to requiring faster processors and more efficient search algorithms.

Each store-and-forward switch node is typically programmed to detect, report, and record any fault conditions, including presence of excessive noise, system tampering, and link failure. Switch nodes must also become aware of each other's status. For example, in order to notify its neighboring nodes that the node is *alive*, each node can periodically send each neighboring node the serial number of the last message it received from that node.

A common capability of store-and-forward switches is supporting message priority. Based on parameters such as delay (or loss) tolerance or message length, every message can have a particular priority level. Messages with higher priority must be treated first and forwarded in minimum time. Supporting message priority can add considerable complexity to message storage strategies, requiring separate listing for each priority group. Furthermore, the system must allow high-urgency messages to interrupt others during their transmission. The interrupted messages will be automatically retransmitted as soon as possible, with no further action by the sender. A system that does not support message priority can simply handle incoming messages on a first-in-first-out basis.

A store-and-forward switch can also perform various statistical analysis, billing operations, and status reports. For example, it can examine each message for its number of characters in order to charge the sending party. It may also analyze message headers to gather statistical information on various network links. The status report can include the status of facilities, error statistics, and message counts.

An important function of a store-and-forward switch is that it can intercept a message for various reasons. For example, if the destination node is temporarily unavailable, the switch can store the message until the destination

is working again. The switch can also reroute the message to other alternative recipients acquiring the same message. Message interception can also be considered for cases where the destination node has moved and it is no longer in its previous location. In such cases, assuming the system can locate the user, the message will be redirected to the new location.

A store-and-forward switch that can also act as a message gateway is often called a *transactional switch* (Tomasi, 2004). In addition to storing messages and performing message routing, a transactional switch can change the message format and bit rate and then convert it to an entirely different form. Hence, through message reformatting, message switching can effectively allow for translating messages between dissimilar high-level applications and protocols.

Message-based Protocols and the OSI Model

In order to better understand functionalities of different message-based protocols, in this section we conform these protocols to the seven-layer Open Systems Interconnections/Reference Model (OSI/RM). Different layers of the OSI model are depicted in Figure 4. As we mentioned before, message transmission and message switching over the physical layer are performed one hop at a time. Each intermediate store-and-forward switch node receives the entire message, stores it, and forwards it to the next hop. A network using this technique is called a store-and-forward network.

Data-link layer protocols in message-switched networks deal with the algorithms (e.g., error detection and message flow regulation) for achieving reliable and efficient message passing between two neighboring store-and-forward switch nodes. Another important function of such protocols is providing proper services to the network layer (Tanenbaum, 2002). Such services include the following: (a) unacknowledged connection-less service (the sender sends the message randomly and expects no response back from the receiver); (b) acknowledged connection-less service (the sender sends the message randomly and expects some kind of response back from the receiver); (c) connection-oriented service (prior to sending the message, a direct circuit must be established between the two adjacent nodes).

Depending on the data-link protocol, different retransmission mechanisms, if any, may be implemented. A simple approach is to send an acknowledgement frame back to the sender. In this case, the sender can assume proper reception of the message by the downstream node and remove its copy of the message. In some networks the retransmission occurs when a negative acknowledgement or simply *nothing* is received.

The main functionality of the network layer in message switching is to provide routing algorithms, such as source routing and shortest-path routing. Based on the routing procedure, the intermediate store-and-forward node must determine the next hop and forward the message there. The network layer is also responsible for supporting message broadcasting and message multicasting.

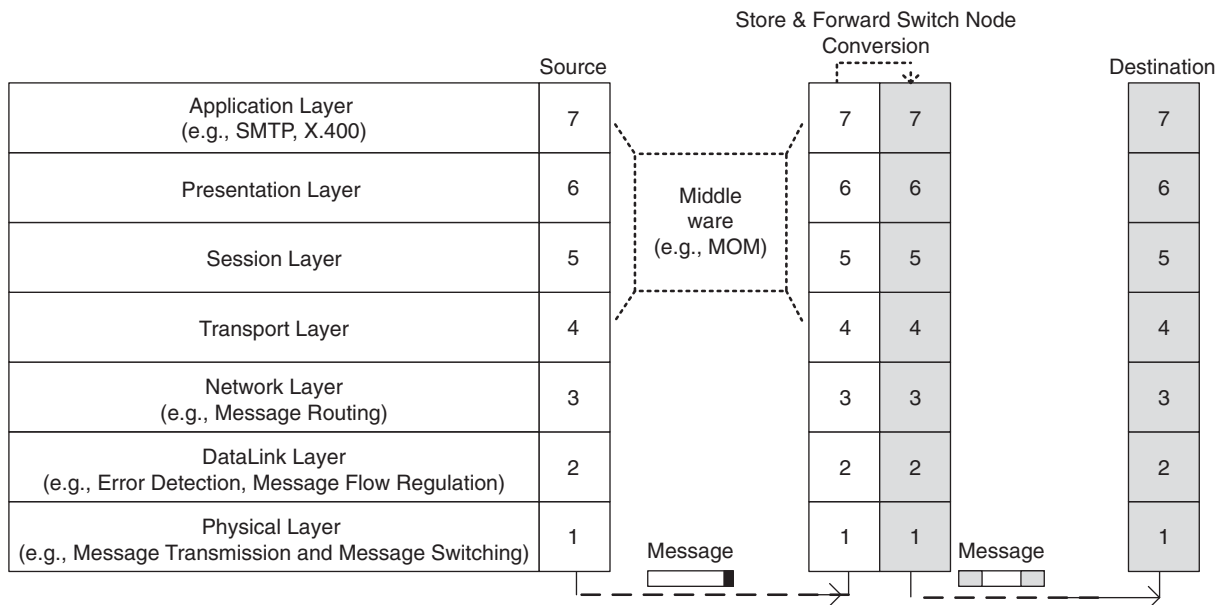

Figure 4: Store-and-forward technology can be implemented at different layers of the OSI model

In general, message-switched networks do not require an official transport protocol. In such networks, each pair of interconnected store-and-forward switch node can negotiate the use of any desired transport protocol (or none at all), as long as the underlying communication is reliable.

Because in message switching the entire message is delivered and stored at the next hop, message-based protocols can offer features beyond the transport layer. These protocols are typically application-aware and hence, they can operate in various transmission environments. For example, they are capable of tolerating temporary node unavailability or converting message format. Two common examples of message-based protocols are X.400 and SMTP, which will be discussed in Store-and-Forward Electronic Mail later in this chapter.

The store-and-forward technology can also be implemented in *middleware*. Middleware is a software that provides a translation mechanism, interconnecting application software across a network, such as a server/client network, and creating a single-system image. One category of middleware that utilizes store-and-forward technology and provides program-to-program communications by message passing is called Message-Oriented Middleware (MOM). We discuss MOM in Message-Based Client/Server Systems later in this chapter.

Figure 4 shows that an incoming message into the store-and-forward switch node can be entirely reformatted prior to its retransmission. In many systems a copy of each message will be stored until its reception by the next hop is acknowledged. Message storage can be performed at different layers, including the network layer or application layer. Data-link and possibly other higher layer protocols are responsible to provide message status information. Note that middleware mediates between top layers of the OSI reference model.

MESSAGE-SWITCHED NETWORKS AND THEIR APPLICATIONS

The basic concept of store-and-forward implemented in message switching has been around since the early use of smoke signals and beacons. The postal delivery system in the eighteenth century, which was not significantly different from the current postal system, also used store-and-forward techniques. In this system a piece of mail (e.g., a parcel) is dropped off at the local post office. The mail will be picked up and taken to the next post office closest to the destination when the delivery service becomes available. Eventually, the mail is delivered to the recipient or stored in the destination post office, waiting for pickup by the recipient. We should note that in the postal delivery system example, proper delivery to the next station is typically assumed.

In the late eighteenth century, semaphore networks became popular. These networks used visual signals (flags, lamps, heliographs) to convey messages between operators in towers. Each tower, in turn, would relay the message to the next until the message was delivered.

The store-and-forward method was also implemented in telegraph message switching centers, commonly known as torn-tape centers (Davis and Barber, 1973). In these centers operators tore message tapes from tape punches on incoming circuits and stored them in output baskets according to their outgoing address. Then, when the dispatcher clerk became available, the messages were keyed in an appropriate circuit to the next center. Telegraphy messages were also called telegrams or cable grams.

The development of mechanical teleprinters, also known as teletypewriters or teletypes, resulted in an increase in the message carrying capacity of telegraph lines. Furthermore, by using the teleprinter terminals the operators were no longer required to know special

codes (e.g., Morse code). The telex, short for teleprinter exchange, was introduced as a public service using teleprinters connected through automatic exchanges (telex switching facilities). Using the telex network a subscriber can type out the telex number or code for the called party, wait for an acknowledgment from the called machine, and then transmit. The printed message is often stored at the other end even if the called teleprinter is not staffed.

Advancements in digital computers and digital storage devices made radical improvements in message switching systems. During the 1960s and 1970s, the store-and-forward technology was largely promoted by Western Union, which traditionally was a message carrying organization. Due to long distances between cities in the United States, Western Union primarily was focusing on store-and-forward techniques to maximize line utilization in order to offer telex and telegraph, as well as variety of computer-based services.

Today, although many major networks and systems are packet-switched or circuit switched networks, their delivery processes can be based on message switching. For example, in most electronic mail systems the delivery process is based on message switching, while the network is in fact either circuit-switched or packet-switched.

Store-and-Forward Networks

Message switching technology has been the forerunner of today's advanced data communications. It set the trends for packet switching technology and more sophisticated networks of the twenty-first century. In fact, many of the early data networks and communications services were actually built upon the message-switched concept and store-and-forward technology. In the remainder of this section, we first discuss a few of such networks, which are considered as major breakthroughs in development of current complex data communications networks. Then, we examine some of the common communications protocols that are designed based on store-and-forward technology.

AUTODIN Network

The Automatic Digital Network (AUTODIN), developed in the mid-1960s, is one of the largest and most complex message switching systems. Using store-and-forward switching technology, AUTODIN provided a message-based worldwide communication network for the U.S. military, handling the data communication needs for the Department of Defense and other Federal organizations (the alternative system to handle voice communications was AUTOVON) (FAS, 2003). AUTODIN has also been used by other major agencies including the NSA (National Security Agency), the DIA (Defense Intelligence Agency), and NATO (North Atlantic Treaty Organization).

AUTODIN was originally considered as a dedicated backbone network serving primarily for secret data transmission. All switches and routers in the network were controlled by a system called the AUTODIN Switching Center. The system was designed to run at 2400 bits-per-second (bps); however, speeds up to 9600 bps were possible.

The header of each message sent by AUTODIN included source, destination, security classification, priority

statement, and a subject line. A very important aspect of AUTODIN was providing highly secure communications. Hence, all external connections to the network from telephone lines were subject to strong encryption techniques.

For the past several decades, AUTODIN has been regarded as a highly sophisticated message-switched network. It also had major contributions in advancing data communications. For example, in 1966 AUTODIN was one of the first systems that allowed electronic text messages to be transferred between users on different computers.

In 1982 an enhanced program, known as AUTODIN II, aiming to improve the system performance and security, was terminated in favor of using packet-based ARPANET technology. As of 2003, many AUTODIN switching sites have been shut down. The intention is to replace the old system with the Defense Message System (DMS). DMS is based on implementations of the OSI X.400 e-mail, which provides message services, through supporting multimedia messaging, directory services, and different grades of services, to all Department of Defense users.

SITA and AFTN Networks

Société Internationale de Télécommunications Aéronautiques (SITA) was originally established in 1949 by a group of airlines. The purpose of the project was to provide computer-based seat reservation service to facilitate the sale of seats on airplanes and exchange of operational information (Martin, 1985). SITA organized a common global service supported by a low-speed message switching network that was based on teletype message format generated by teleprinters.

Aeronautical Fixed Telecommunication Network (AFTN) is also another example of a worldwide message switching network. After World War II, following SITA experience, AFTN was introduced to support exchange of messages between aeronautical fixed stations and aircrafts. AFTN is composed of aviation entities, including aviation service providers, airport authorities, and government agencies. It exchanges vital information for aircraft operations such as urgency messages, flight safety messages, meteorological messages, flight regularity messages, and aeronautical administrative messages (Bush, 2003).

Today, the airline industry continues to use teletype messages over SITA and AFTN as a medium for communicating via messages. These teletype messages are machine-generated by automatic processes. The International Air Transport Association (IATA) is responsible for standardizing the message format throughout the airline industry. In the last several decades, however, as the packet switching has become the standard means of telecommunications, both SITA and AFTN networks have undergone major reengineering and their nodes have been replaced to support packet switching.

USENET Network

USENET (USER NETwork) began in 1979 as a bulletin board between two universities in North Carolina. It is basically a public access network on the Internet and other TCP/IP-based networks that provides user news and group e-mail.

USENET provides a set of protocols for generating, storing, retrieving, and exchanging news articles among a widely distributed user group. The format of news messages and e-mail messages are structurally the same. Hence, USENET permits news messages to be carried the same way as e-mail messages. The only difference is the additional header fields indicating which newsgroups (a repository of articles posted by the users) the message belongs to.

USENET is considered as one of the first peer-to-peer applications. In this case the *peers* are the servers and can be accessed by the users. A major advantage of USENET is that it reduces network traffic and eliminates the need to store a copy of each article on every subscriber's system. This is done by putting all articles in a central database and allowing users to access the database to get the articles they need (Tanenbaum, 2002).

Originally, USENET relied on a message exchange system called UUCP (UNIX-to-UNIX Copy Program). UUCP is a *flood broadcast* mechanism. Hosts send news articles they receive to other hosts, which in turn forward the news on to other hosts that they feed. Usually, a host receives duplicates of articles and must discard those duplicates. This can be a time-consuming process, resulting in waste of bandwidth.

Today, message delivery in USENET is primarily handled by an Internet protocol called NNTP (network news transport protocol). NNTP uses an interactive command and response mechanism that lets hosts determine which articles are to be transmitted. A host acting as a client contacts a server host using NNTP, and then inquires if any new newsgroups have been created on any of the serving host systems.

Performance-Challenged Networks

Performance-challenged networks (or simply *challenged networks*) are interconnected networks in which end-to-end latency, bandwidth asymmetry, and/or path stability are substantially worse compared to typical Internet environments. Such network environments are particularly common in space or ocean (acoustic underwater) communications, sensor networks, and military tactical communications, all of which lack an infrastructure.

In challenged networks the signal propagation time is comparatively long as a result of either long physical separation of end nodes, as in space, or because of slow transmission speed, as in water. Consequently, the total transmission time in such networks can take literally hours or perhaps days. Protocols such as TCP/IP that expect acknowledgments may not be appropriate for such environments. This is mainly because too many timeouts can occur because of heavy congestions in the low capacity links. Another issue with challenged networks is path instability, which is generally the result of short node lifetime or mobility. For example, in sensor networks many of the sensors may run out of battery power after some period of time (Fall, 2003).

One approach to support interconnecting challenged networks and their interoperability is called delay tolerance networking (DTN), which is based on message switching. The use of message switching for these networks allows all the small request/responses to be aggregated,

hence reducing the number of packets being routed through the network (Fall, 2002). Aggregated messages are often stored, scheduled, and eventually forwarded toward the destination node. The other benefit of implementing message switching is that it does not require pre-established end-to-end state of the network. Using store-and-forward technology, each node discovers its available neighboring nodes and forwards them the messages. Research in challenged networks is a relatively new area and is still being investigated.

Message-Switched Protocols

In this subsection we look at some of the most common protocols that are based on store-and-forward technology. As a result of their vast applications, we only focus on three specific systems: electronic mail systems, message-based client/server systems, and wireless messaging systems.

Store-and-Forward Electronic Mail

With the advancement in digital technology and digital data communications, sending electronic data, text messages, documents, as well as voice and images, collectively known as electronic mail (e-mail), became very popular. The first e-mail systems simply consisted of file transfer protocols. Over the years, many new protocols were developed for more ambitious e-mail systems. The majority of these protocols have been designed based on store-and-forward technology. In the following paragraphs, we briefly discuss two e-mail delivery protocols: X.400 and SMTP.

X.400. The main motivation in development of X.400 was to create a common standard that would allow different electronic mail systems to communicate together. X.400 (also referred to as message-oriented text interchange systems [MOTIS]) is a set of standards developed by ITU-T (the International Telecommunications Union-Telecommunications, formerly known as CCITT), which includes protocols dealing with message handling systems (MHS). These standards are designed to exchange messages (e-mails) between different store-and-forward servers and networks. In its original form, X.400 outlines a set of basic message-handling characteristics that establish functionalities including the following:

- Store-and-forward delivery of messages to multiple recipients
- Conversion of message content to allow message transfer between dissimilar sending and receiving devices (fax, telex, PC)
- Delivery-time control

X.400 was first published in 1984 (Red Book) and a substantially revised version, known as X.400/88, was published in 1988 (Blue Book). In 1992, new features and updates were added (White Book) (Betanov, 1992). Although X.400 was originally designed to accommodate OSI model transport services, today it is typically run over TCP/IP.

A network model defined by X.400 consists of a number of basic elements including user agent (UA), message transfer agent (MTA), and message store (MS), as shown in Figure 5. The UA is a program that allows the user to compose, send, and receive mail. The MTA is the electronic post office, accepting the e-mail from user agents and making sure it is delivered. MS, which often co-resides with MTA, maintains electronic mailboxes for each user. When a message is delivered, it may pass through multiple MTAs, each of which reads the message address and passes it to another message transfer agent, until the message reaches its destination. As indicated by Figure 5, messages can be transmitted directly by MTA to the UA recipient or, alternatively, they can be passed on to MS (the equivalent of a mailbox) which makes it possible to store the message. Incoming messages can be stored in these mailboxes until the user logs in. A collection of all message transfer agents cooperating to relay the messages until their destinations is called the message transfer system (MTS).

Figure 5 also shows some of main protocols of X.400. These are P1, defining the communication between MTAs; P3, standardizing the connection between the user agent and MTA; P2 standardizing the (virtual) protocol between the UAs; and P7, describing the interaction between the user agent and message store (Tanenbaum, 2002).

At its early development, X.400 was widely implemented, especially in Europe. However, as e-mails became more popular, many of X.400 features, such as structured addressing and central control, made it more complex for everyday usage. On the other hand, advances in the Internet-based e-mail protocols, in particular simple mail transfer protocol (SMTP), made X.400 less popular. Ironically, the same features which made X.400 less popular, made it attractive for special networks such as military and aviation. In fact, extended versions of X.400, such as military message handling systems (MMHS) and aviation message handling systems (AMHS), are still under research and development. These protocols employ integrated security capabilities, including message routing, password management, and provisioning of public key infrastructure (PKI).

SMTP. Simple mail transfer protocol (SMTP) is considered an application-level protocol, which runs over packet-based TCP/IP. SMTP was developed by IETF (Internet Engineering Task Force) and has become the de facto standard for mail transfer on the Internet. Virtually all e-mail systems that send mail via the Internet use SMTP to send their messages. SMTP is used for forwarding messages from one host to the other and writes them to a message store (e.g., mbox or Maildir). However, SMTP does not provide the functionality of allowing users to retrieve mail. The post office protocol (POP) has been developed for retrieving messages from the message store.

Although SMTP is the most prevalent of the e-mail protocols, it lacks some of the rich features of X.400. A primary weakness of SMTP is the lack of support for non-text messages. Multipurpose Internet mail extensions (MIME) has been introduced to supplement SMTP allowing the encapsulation of multimedia (non-text) messages inside of a standard SMTP message (Parker, 2002).

X.400 and SMTP have similar features but also unique features in themselves. Generally speaking, X.400 is a more complex protocol and it makes it harder for users to fake e-mail addresses and contents, compared with the situation in SMTP. For a complete discussion on SMTP protocol, please refer to "SMTP (Simple Mail Transfer Protocol)".

Message-Based Client/Server Systems

Many client/server systems use middleware to exchange messages. Middleware is used to simplify the complexity of dealing with communication protocols and layers of software. Broadly speaking, middleware software is defined as the *glue* between software components or between software and the network or it is the *slash* in client/server (MRC, 2004). One category of middleware that provides program-to-program communication by message passing is called message-oriented middleware (MOM). MOM is based on message queuing and store-and-forward technology. MOM is a non-blocking asynchronous form of communication. Hence, every node in the system can randomly send message to the queue or

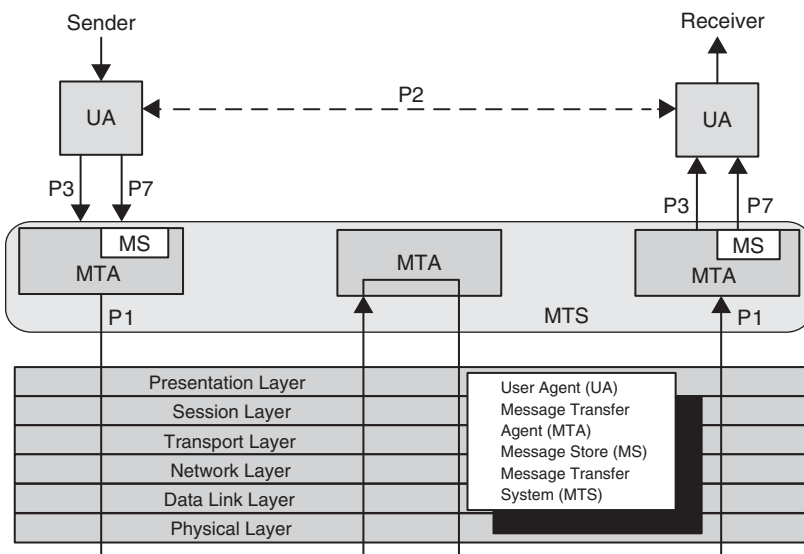

Figure 5: A general network model defined by X.400

taking message from queues. Note that the queue can be a part of the client or a dedicated server. Message storage and queuing can be persistent (logged on disk) or non-persistent (in memory). Persistent messages are slower but they can be recovered in case of power failures.

The message flow in MOM messaging products can have different types, including send-and-pray (no response about the message is required), send-and-nay (a response is required if there is something wrong with the message), and send-and-say (response is mandatory).

Store-and-Forward Wireless Messaging

Today, many wireless applications and services are based on store-and-forward technology in order to reliably transfer messages between end-users. A popular example is short message service (SMS). Although, SMS is being supported by many digital-based mobile communications systems, it was introduced as a datagram service in the GSM (global system for mobile communications) system. SMS is a text message service that enables short text messages (up to 160 characters in length) to be transmitted and received by a cell phone. Similar to e-mail, short messages are stored and forwarded at SMS centers, which means messages can be retrieved later if the user is not immediately available (MWR, 2004). SMS messages travel to the cell phone over out-of-band control channels, separated from voice channels. SMS has been broadly used in Europe and Asia for many years. In North America, SMS was made available initially on digital wireless networks built by early pioneers such as BellSouth Mobility, PrimeCo, and Nextel, among others.

Paging systems capable of storing and delivering messages (or pages) are also examples of store-and-forward wireless systems. A wireless pager receiver can be activated and alert its user via a tone or a vibrator. This is typically called a one-way paging system. Pager activation can be done using a telephone or a PC. In store-and-forward based paging systems, if the network cannot reach the user to deliver the message, it stores the message until the user can be reached (Taylor et al., 1996). Some paging systems have SMS capability and allow displaying small alphanumeric messages. Two-way paging systems include an acknowledgement feature that allows the user to acknowledge the receipt of the message.

Wireless sensor networks (WSN) also use store-and-forward technology. WSN are mesh networks of small sensor nodes communicating among themselves using RF communication. Sensor nodes can be deployed in large scale (from tens to thousands) to sense the physical world, for example, monitoring, tracking, and controlling. The data messages gathered by each sensor node will be periodically exchanged between nodes or passed on to intermediate nodes. Intermediate nodes can aggregate small data messages together prior to retransmitting them to the next node (Zhao and Guibas, 2005).

Store-and-forward technology has also been considered to be implemented in satellite communications systems in order to ensure higher reliability and network robustness. For example, message switching is recently being investigated for inter-satellite networks, where messages are transmitted between two communication

satellites, as opposed to communications between a single satellite and Earth stations (Charles, 1999). Message switching is also being considered for interplanetary networks, a high-bandwidth infrastructure designed to link Earth's Internet to other parts of our solar system.

Research suggests that store-and-forward technology can also enhance the wireless range of low-cost short-range technologies, such as WiFi (IEEE 802.11). One approach is simply relaying the data between multiple wireless devices over long distance. A more cost-effective approach is to transmit data over short point-to-point links between mobile storage devices called mobile access points (MAP). Through the use of low-cost WiFi radio transceivers, the data carried by the MAP is automatically and wirelessly transferred at high-bandwidth for each point-to-point connection (Pentland, 2002). The motivation in utilizing this approach is providing a very low-cost and affordable solution to resolve the last mile connectivity problem, particularly in poor rural areas.

PERFORMANCE OF MESSAGE-SWITCHED NETWORKS

In this section we examine the performance of message-switched networks in terms of delay and peak traffic load.

Delay Performance

Figure 6 depicts the transmission of a message across four nodes. Three types of delays can be identified on the diagram: (a) propagation delay—the time it takes a signal to propagate from one node to the next; (b) transmission delay—the time it takes for a transmitter to send out a message (e.g., it takes 0.1 sec. to transmit a 10,000 bit message onto a 100 kbps line); (c) node delay—the time it takes for a node to perform the necessary processing as it switches data plus the message storage time. Hence, the total delay will be the sum of all propagation and transmission delays at each node plus the sum of node delays at each switch node (Rosner, 1981).

As Figure 6 indicates, prior to retransmission, the entire message must be received at each switch node. This results in a large end-to-end delay, particularly if the message size is very large. In fact, under heavy load, when the node delay is not negligible, the total delay using message switching can be significantly longer than for circuit switching, which requires time to setup and tear-down a connection.

Node Delay

An important factor impacting node delay is unavailability of the next hop or the destination node. The store-and-forward switches in a message-switched network avoid repeated attempts to send messages to the next hop. Hence, if the next node is not available, the message retransmission is simply delayed. Clearly, as the total number of messages in the network increases, the average node delay through the network will become longer until no storage resources are available and message dropping occurs. This is illustrated in Figure 7a.

Figure 6: Event timing diagram in message-switched networks (the example assumes all the link speeds and lengths are the same; node delays are assumed to be negligible)

Figure 7: (a) Delay in message-switched networks as the load increases; (b) traffic characteristic as a result of store-and-forward switches

Another important factor affecting the node delay in a store-and-forward switch is network congestion. That is the case where switches cannot deliver as fast as messages are arriving. When congestion occurs, the system continues to accept new messages, as long as its storage capacity allows. In message switching new messages will be stored until free resources are available and the delivery is ensured; hence, no message blocking occurs as long as sufficient storage capacity is available. As the load of the network increases, more messages will have to wait for available processing resources and free links. The

result is an increase in the message delivery time through the network.

Another way of looking at a network with store-and-forward switches is to regard it as a large distributed set of storage facilities, which gradually fill as the load on the network increases. Consequently, the peak load is shifted in time by an amount depending on the available storage (Davis et al., 1973). Figure 7b illustrates this point by showing how a peak load is reduced, but at the expense of being delayed. The area under each of the two curves represents the total number of messages delivered. Clearly, this area will be the same for both curves.

Comparison of Message, Packet, and Circuit Switching

Message-switched networks provide a number of advantages over circuit-switched networks. For example, message-switched networks provide more efficient use of network resources. This is a result of their inherent store-and-forward capability. As new information enters the network for future delivery, the message storage process creates a reservoir of traffic. This reservoir tends to remove the gaps between new message arrivals onto the network. In addition, it smoothes the peak network load, leading to some degree of traffic regulation over the network.

When traffic becomes heavy on a circuit-switched network, some connection requests are blocked; that is, the network refuses to accept any additional connection requests until the load on the network decreases. In a message-switched network, messages are still accepted as long as the storage capacity is available but delivery delay increases. As a result, message-switched networks translate potential message blocking into potential delay. As long as the total end-to-end message delay meets the user delay tolerance, message delaying can be far more convenient than message retransmission due to blocking.

Another attractive feature of message-switched networks is that in these networks each intermediary node can perform protocol translation. Since each intermediary node processes the entire message, it can perform

any required line code, transmission speed, or protocol conversions between incompatible nodes. Therefore, message switching can be a potential solution for less robust communication environments. In circuit switching, protocol conversion is only possible through protocol gateways.

In message-switched networks, unlike circuit switching, simultaneous availability of sender and receiver is not required and the network can store the message pending the availability of the receiver. Moreover, features such as broadcasting, data auditing, and data rerouting can be supported by message-switched networks much more easily and typically require no major architectural modifications.

The difference between message switching and packet switching begins with the characteristics of messages and packets themselves. Messages are units of information with unrestricted lengths, whereas packets have maximum length size. Furthermore, in a message-switched network the network is responsible for the message and typically no responses or feedbacks exist. Consequently, in message switching, rather than minimizing transit time of the message, its guaranteed delivery is emphasized. On the other hand, packet-switched networks aim to deliver packets with minimum delay and do not hold packets for delayed delivery. Table 1 compares the main characteristics of message, packet, and circuit-switching technologies.

Figure 8 illustrates the transmission of data across four nodes using circuit-switched and packet-switched networks. An important characteristic of circuit switching

Table 1: Comparison of Message, Packet, and Circuit Switching (Stallings, 2004; Martin, 1985)

Circuit-Switched Networks	Message-Switched Networks	Packet-Switched Networks
Communication is performed through a dedicated path.	No dedicated path exists.	No dedicated path exists.
Provides real-time or continuous transmission of data.	Too slow for real-time or interactive data transmission.	Provides near real-time data transmission.
No data storing is required.	Messages are stored for later retrieval.	Packets are queued for delivery; they are not stored.
The switch path is established for the entire connection time.	The route is established for each message.	The route is established for each packet.
For small messages, the data transmission time is negligible compared to the time required to setup and tear-down the connection.	The message delivery time can be substantially long.	The packet delivery time is very short.
The connection is blocked if the end-user is busy or not available. Once the connection starts, no blocking may occur.	No message blocking can occur as long as the storage capacity is sufficiently large.	Packet blocking can occur, however, the blocked packets will be retransmitted to the end-user.
As the network load increases, more blocking can occur.	As the load increases, messages on average experience longer delivery delay.	As the load increases, packets on average experience longer queuing delay, although still very short compared to message switching.
The length of transmission is unlimited.	Messages have no theoretical maximum length and can be very long.	Packets have a maximum length.

Figure 8: Event timing diagram in (a) a circuit-switched network and (b) a packet-switched network; we assume no loss of data occurs

is the need to setup an end-to-end path. During this time interval (setup time), depicted in Figure 8a, the system is ensuring path availability.

In packet switching, shown in Figure 8b, no physical path is established in advance between sender and receiver. Hence, unlike message switching (Figure 6), each node along the route may begin transmission of a packet as soon as it arrives.

CONCLUSION

In this chapter we examined the basic concepts of message-switched networks. We surveyed their advantages and disadvantages and demonstrated their applications. We also described different elements of a message-switched network and examined their basic functionalities. Although packet switching is becoming the dominant switching scheme, message switching is still considered for many dedicated networks.

GLOSSARY

ARPANET: The Advanced Research Project Agency Network created by the U.S. Department of Defense. This organization is credited with creating the Internet in 1969.

CCITT: Short for *Comité Consultatif International Téléphonique et Télégraphique*, an organization based in Geneva, Switzerland, that sets international communications standards. CCITT changed its name to International Telecommunications Union (ITU), the parent organization, on March 1, 1993.

Datagram: A sequence of bytes that constitutes the unit of transmission in the network layer.

Exchange: A room or building equipped with manual or automatic switching equipments that can interconnect incoming communication lines as required.

IETF: Internet Engineering Task Force is a large, open international community of network designers, operators, vendors, and researchers, which sets standards for the Internet. It is also responsible for much of the work done on TCP/IP.

Peer-to-Peer Architecture (P2P): It is a type of network architecture in which each workstation has equivalent capabilities and responsibilities.

Protocol: A formal and pre-agreed set of rules that govern the communications between two or more entities. The protocol determines the meaning of specific values occurring in specific positions in the stream, the type of error checking to be used, the data compression method, how the sender will indicate that it has finished sending a message, and how the receiver will indicate that it has received a message.

Telegram: A message transmitted by telegraph system.

Teleprinter: A typewriter-like terminal with a keyboard and built-in printer. It was used to communicate typed messages between terminals through a simple point-to-point electrical communication channel, often just a pair of wire. A teleprinter terminal is also called teletype or TTY machine.

FURTHER READING

Many of the original publications on message switching and store-and-forward technology belong to early 1960s and 1970s. Several comprehensive discussions on these topics are found in Davis et al. (1973) and Martin (1985). A basic analytical model for a message-switched network in terms of data loss and delay is provided by Rosner (1981). Stallings (2004), Tomasi (2004), and Martin (1985) offer a list of advantages and disadvantages of message switching and compare the performance between message, packet, and circuit switching. One of the first detailed tutorials on store-and-forward switch node functionalities can be found in Shafritz (1964).

Routing techniques in message-switched and packet-switched networks are very similar. Various routing techniques are described in Tanenbaum (2002).

Examples of message-switched networks, including SITA and AUTODIN, along with detailed discussions of their technical specifications and evolutions, are provided in Martin (1985). FAS (2003) is specifically dedicated to the history of AUTODIN. Bush (2003) offers background information on AFTN. Introductory information about USENET, including its commands and protocols, can be found in Tanenbaum (2002). Betanov (1992) and Parker and Siyan (2002) offer a comprehensive discussion on X.400 and SMTP protocols and their differences. More information about middleware and MOM can be found in MRC (2004).

Recent investigation on implementing message switching in challenged networks and satellite communications can be found in Fall (2003), Fall (2002), and Charles (1999). More information regarding the paging systems and wireless sensor networks can be found in Taylor (1996) and Zhao (2005), respectively. A number of books about short message services are listed in MWR (2004). Moreover, an interesting work demonstrating how store-and-forward technology can be used to provide a low-cost solution to resolve the last mile continuity problem in rural areas can be found in Pentland et al. (2002).

INTRODUCTION

General Concepts

Frame relay is a connection-oriented end-to-end WAN protocol that operates at the two lowest layers of the OSI reference model—physical and data link layers. Developers of the protocol came up with its name “frame relay” as a result of the nature of the technology, where data is being transferred in “packets” or “frames” traversing the WAN. In fact, frame relay was developed as part of BISDN (Broadband Integrated Services Digital Network) described in “BISDN (Broadband Integrated Services Digital Network),” and is a classical implementation of a packet-switched technology described in this chapter. Packet-switched networks establish logical connections (virtual circuits) between devices as opposed to connecting them by dedicated leased lines (Peterson and Davie, 1996). This technology reduces the network complexity (and certainly price) required to connect multiple devices in a mesh network environment.

By implementing variable length packets, frame relay was designed with data networks in mind. Nevertheless, there were attempts by several vendors to use frame relay networks for transferring voice and even video. However, utilization of frame relay networks for voice or video transfer proved to be inefficient and short-lived. Therefore, today this technology is being used predominantly, if not exclusively, for data transfer only.

Historical Overview

As a successor of the original packet-switching X.25 technology, developers of frame relay monopolized on a more reliable digital network infrastructure emphasizing more efficient utilization of the network and deemphasizing packet integrity and error correction requirements. Thus, frame relay offers services at layers 1 and 2 of the OSI reference model, whether X.25 offers services at the

network layer as well. Therefore, in frame relay networks error correction is performed at the end points offering superior performance and much better transmission efficiency than X.25.

Initial proposals for frame relay standard were presented in 1984 to the CCITT (Comité Consultatif International Téléphonique et Télégraphique)—now referred to by the name of its parent organization as ITU (International Telecommunication Union). The ITU was founded in 1865 and became a United Nations agency in 1947. Telecommunications standardization functions were formerly performed by the CCITT. However, after the 1992 reorganization of the ITU CCITT no longer exists as a separate entity.

Frame relay is a classical example of a technology developed from an existing protocol suite adopting to a modern environment and addressing the ever-growing needs for higher efficiency and network throughput. The original packet-switching technology X.25 was developed to allow cost-efficient connectivity of relatively unsophisticated computer systems over poor quality analog lines. Therefore, X.25 networks required error correction at many levels and nodes along the virtual circuit. Contrary to X.25 frame relay was developed in a more modern environment, with more sophisticated computer systems and higher quality digital telecommunications lines, enabling typically less expensive, but much more efficient and fast data transfer. In fact, frame relay is sometimes being referred to as fast packet switching.

The definition of frame relay in the so-called Blue Book, published in 1988 by CCITT is very vague. It indicates that on top of a BISDN network there may be various services, with frame-oriented service being one of them. In the early 1990s, this fairly vague definition was taken up by consortium of four companies Cisco Systems, Digital Equipment Corporation (now part of HP), Northern

Telecom, and Stratacom (now part of Cisco) and expanded by ANSI T1S1.2 subcommittee into a concrete interface definition, which subsequently became what we know today as the frame relay protocol (Malamud, 1992).

Indubitably, IBM's strong endorsement and support of the frame relay protocol had contributed to its dramatic success in the 1990s. By allowing encapsulation of its proprietary SNA (Systems Network Architecture) protocols into frame relay and wide implementation of this technology across IBM data communications family of products, that is, IBM 3174 terminal controllers, 3745 front-end communications controllers, and their 3172 LAN interconnect controllers, it allowed SNA users to take advantage of a low-cost multiplexed access network. Thus, frame relay networks quickly replaced the vast networks of multidrop SDLC leased lines used by SNA customers previously (Rabinovitch, 1995).

Frame Relay and the OSI Reference Model

Frame relay protocol specified in CCITT recommendations I.122 and Q.922 adds relay and routing functions to the data link-layer 2 of the OSI reference model.

Layer	Name	Function	Examples
...
3	Network	Controls data transfers between computers	X.25, IP
2	Data link	Protocols for operating data communications lines	ISDN, ATM, frame relay
1	Physical	Physical medium for data transport	Connectors for copper wire, fiber optic cables, wireless

In contrast to X.25 that includes implementation of the network layer in OSI reference model with all the overhead associated with assembly/disassembly of packets and routing information, frame relay protocol has significantly lower overhead using a group of two octets only for data link control at layer 2. Frame relay performs simple and fast error checking, and if a frame is full of errors, it's being discarded.

PACKET SWITCHING AND NETWORK DESIGN CONSIDERATIONS

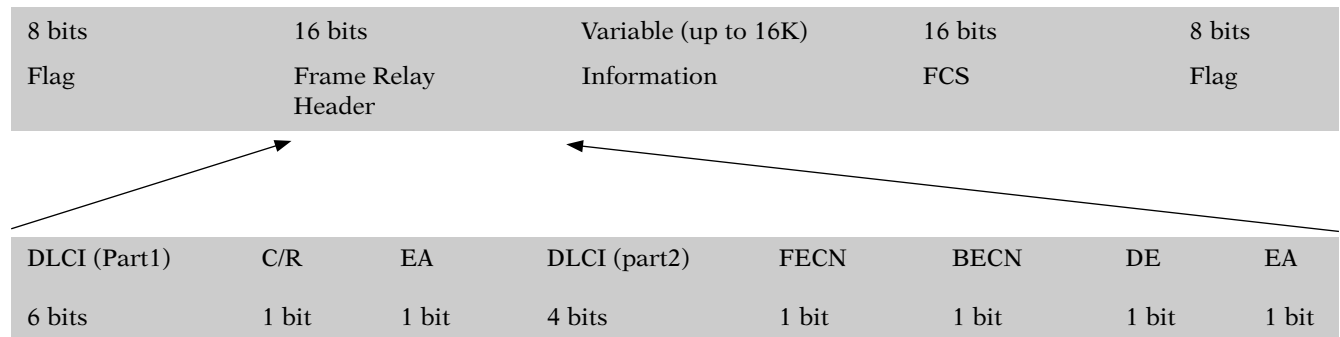

Protocol Description

Capitalizing on modern and more reliable network infrastructure frame relay developers aimed at an improved, faster, and more cost-efficient data transmission protocol than X.25. Thus, with frame relay data being sent in variable-size frames, error-correction, and retransmission requests are performed at the end nodes, which only speed up the transmission and reduce the sophistication requirements and obviously costs of the network devices.

Frame relay packet structure is based on the LAP-D (link access procedure-D-channel) protocol, which is a layer 2 protocol of the ISDN suite almost identical to LAP-B (link access protocol—balanced).

8 bits	16 bits	Variable	16 bits	8 bits
Flag	Address field	Information	FCS	Flag

Frame relay implementation of LAP-D incorporates the data link connection identifier (DLCI) and congestion bits in the address field. Consequently, the frame relay header is 2 bytes in length and has the following format:

- Flag (X'7E') is the frame delimiter

DLCI is a multipart field that identifies virtual channel mapping onto the physical channel. Several virtual connections can be multiplexed over the same physical channel. And because DLCI values have local significance only devices at the different ends of a virtual channel may use different DLCIs for the same virtual channel. Valid values for DLCI are as follows:

- 0 – reserved for ANSI Annex D and ITU Annex A link management
- 1–15 – reserved
- 16 – 1007 any PVC
- 1008–1018 – reserved
- 1019 – 1022 reserved for LMI multicast
- 1023 – reserved for LMI link management

- EA (extended address) indicates if additional octets follow. EA=0 means more octets will follow. EA = 1 signifies the last octet of the header. Current frame relay implementations use a 2-octet DLCI, however, provisions for longer DLCIs managed by the EA bit are included in the protocol.

- C/R (command/response)
- FECN (forward explicit congestion notification)
- BECN (backward explicit congestion notification)
- DE (discard eligibility)

Frame relay congestion handling mechanism is implemented by utilization of these last three bits in the frame relay header address field.

- FCS (frame check sequence) based on the CRC algorithm allows frame integrity and error detection

As some of the definitions in the original frame relay specifications were quite vague, leaving room for interpretation by different vendors, interoperability “challenges” imposed a need for enhancement of the protocol. The consortium of the four companies, listed earlier in the historical overview section of this chapter (Cisco Systems, Digital Equipment Corporation [now part of HP], Northern Telecom, and Stratacom [now part of Cisco]) developed set of enhancement to the basic frame relay protocol called LMI (local management interface), which is a set of enhancements to the basic frame relay specification often called extensions.

Key LMI extensions include global addressing, virtual circuit status messages, and multicasting.

Below is an LMI frame format:

Flag	LMI DLCI	LAP-D Unnumbered Indicator	Protocol Discriminator	Call Reference	Message Type	Information	FCS	EA
1 octet	2 octets	1 octet	1 octet	1 octet	1 octet	Variable	2 octets	1 octet

New fields depicted in the above figure serve the following functions:

- LMI DLCI identifies the frame as an LMI frame as opposed to a basic frame relay frame. The LMI-specific DLCI value defined in the LMI consortium specification is DLCI = 1023 or DLCI = 0 defined by ANSI and ITU.
- LAP-D Unnumbered Indicator (X'03') sets the poll/final bit to zero.
- Protocol discriminator contains a value indicating that the frame is an LMI frame.
- Call reference (X'00') currently not in use.
- Message type identifies the frame as one of the following message types:
 - Status-inquiry message—device can inquire the status of the network.
 - Status message—response to status-inquiry messages, which includes report type, keepalives, and PVC status messages.

The LMI global addressing extension enables global DLCI values as opposed to values of local significance, where DLCIs were only significant to the physical channel they reside on. As a DLCI value can now be associated with DTE addresses that are unique in the frame relay WAN, the global addressing extension adds important functionality and manageability to frame relay networks. LMI virtual circuit status messages are used to periodically report on the status of PVCs, which in turn allows identification of non-existing PVCs and their removal from active circuits lists.

The LMI multicasting extension enables multicast group assignment that saves bandwidth by allowing routing updates and address-resolution messages to be sent only to specific groups of devices. With LMI multicasting a device sends a frame on a reserved DLCI known as a multicast group. The network replicates the relevant frame and delivers it to a predefined list of DLCIs: that is, multicasting a single frame to a collection of destinations in the group. The LMI multicast extension also transmits reports on the status of multicast groups in update messages.

Flow Control

To achieve high performance at a lower cost, designers of frame relay protocol decided to implement highly simplified flow control. To this extent, there is no link-by-link flow control as such in frame relay networks. Whenever network performance is being degraded as a result of congestion, it simply begins discarding frames that cannot be delivered, whereas end nodes handle all flow control and error correction functions.

One of the main parameters for pricing frame relay connections that is playing a major role in flow control is CIR (committed information rate). CIR, assigned to each DLCI, is usually based on the estimated volume of traffic and obviously cannot exceed the line speed. Frame relay protocol allows bursting above the CIR, but it is always a good idea to plan a frame relay connection according to the estimated bandwidth required for sustainable operations. Capacities of frame relay networks are designed so they can guarantee the CIR at any given point in time, whereas bursting above the CIR is only offered as “best effort” and is depending on conditions and the amount of traffic from other virtual circuits sharing the frame relay infrastructure. Frames entering the network above the CIR value are marked by the traffic originator with the DE bit. In other words, when the network is congested these frames may be dropped.

Some carriers are offering so called “zero” (0) CIR connections, meaning all frames entering the network over a “0 CIR” DLCI are marked with the DE bit and eventually may be dropped. “0 CIR” connections are obviously less

expensive than CIRs with real values, but subscribing to such design is actually a business decision as there is a real possibility that at certain times most of the frames sent over “0 CIR” connections might be dropped. “0 CIR,” however, have assumed great popularity because of the ability of higher layers (frame relay data terminal equipment) to selectively turn the DE-bit “on” or “off.” This results in higher flexibility and ability to selectively send traffic over a “0 CIR” DLCI with the DE-bit turned off, when network conditions allow.

Performance and Congestion Management

Congestion management in frame relay networks includes the following functions:

- Admission control is the principle technique used in frame relay networks to guarantee allocation of required resources. Based on the characteristics of requested traffic and network capacity existing at a certain time the frame relay network decides whether a new connection is possible. Traffic descriptor is a set of parameters communicated to the switching nodes during virtual circuit setup based on statistical characteristics of the new connection. Traffic descriptor consists of the following three elements:
 - CIR: average rate at which frame relay network is capable of guaranteeing information transfer without oversubscription.
 - Committed burst size: maximum rate that can be transmitted during given time.
 - Excess burst size: maximum rate that the network will attempt to carry during given time.
- Explicit congestion notification is imbedded in the frame relay protocol as a congestion avoidance mechanism. When a virtual circuit is established in a frame relay network, the end nodes must monitor the traffic flow to ensure that the actual usage of network resources does not exceed this specification avoiding accumulation of undelivered data within the network.

According to the simple yet smart algorithm of frame relay networks, whenever the network becomes congested to a point where no new frames can be transmitted it simply begins discarding frames. However, as a result of requests from the higher layers of the ISO reference model the discarded frames eventually need to be retransmitted, which, in turn may cause even higher network congestion (Peterson and Davie 1996). To avoid this potentially dangerous network meltdown frame relay includes congestion management functionality. Frames with FECN value of 1 are sent downstream toward the destination location, when congestion occurs during data transmission, thus all downstream nodes including the egress device learn about congestion on the line. Similarly, BECN value is changed to 1 in frames traveling back toward the ingress device on congested paths warning the device to slow down transmission until the congestion situation is resolved. Thus, BECN = 1 has a more significant meaning from an operational stand point and it's very important making sure frame relay devices support

it and know to act properly notifying the higher layers of the OSI Reference Model about the required slowdown in transmissions. FECN is generally implemented in FRDTEs with the following logic: if a frame arrives with FECN = 1, and the retry timer has not expired [within a certain arbitrary or configurable period], then no action is taken; if a frame arrives with FECN = 1, and the retry parameter has not expired, but the period is beyond the “allowable” value, the expiration timer is adjusted; if a frame arrives with FECN = 1, and the retry timer has expired, the expiration timer is adjusted, and retry is reset until the retry timer is exceeded once again (or a subsequent frame arrives with FECN = 1.)

DE bit in a frame relay network comes into play when a network is severely congested. Obviously, dropping discard-eligible frames will relieve congestion in the network so that frames not eligible for discard have a better chance of passing successfully through the network. It is the responsibility of the frame relay DTE to set the DE bits on so that the frame relay DCE (i.e., frame relay frame handler [FRFH]) knows which frames to discard in order to protect itself in case of severe congestion. However, if the FRFH's DLCI queue is full and the DTE continues sending frames with no DE set, the FRFH will mark all frames from that DTE as discard-eligible, notifying the DTE it has exceeded its committed burst. In a frame relay network handling different high-level application protocols, for example, legacy SNA and TCP/IP, during a mild congestion, most SNA applications will slow down by reducing the window size to avoid frame loss and the need to retransmit. However, typical TCP/IP applications ignore the mild congestion and continue to send frames until severe congestion occurs on their DLCI. Then, during severe congestion, FRFH discards TCP/IP frames so that frame loss will cause TCP/IP to slow. “Technically” speaking, response time for the “polite” SNA frame relay users will suffer during mild congestion; however, they are less likely to get into severe congestion trouble. “Impolite” TCP/IP users that cannot throttle down during mild congestion will definitely get into severe congestion trouble causing frame losses, and consequently, retransmissions (Lynch, Gray, and Rabinovitch 1997).

Split Horizon

Configuration of split horizon (Peterson and Davie 1996) is a very important characteristic to keep in mind, while designing partially meshed frame relay networks. By default, split horizon is disabled for frame relay networks, so routing updates can come in and out the same network interface. When the routers learn the DLCIs they need to use through LMI update messages they use inverse ARP for the remote IP address to create routing maps for local DLCIs to their respective remote IP addresses. However, because certain protocols require split horizon enabled, where a packet received on an interface cannot be transmitted out the same interface even if it is transmitted on different virtual circuits, partially meshed frame relay networks cannot be configured for protocols such as AppleTalk or IPX. To overcome such issues, frame relay sub-interfaces can be configured, whereby a single physical interface is now being treated as multiple virtual

Figure 1: Frame relay network "cloud"

interfaces. This type of configuration allows overcoming split horizon rules for legacy protocols so packets received on one virtual interface will be forwarded out another virtual interface, even though both are configured over the same physical interface.

STANDARDS AND STANDARD BODIES

MFA Forum

To speed up the adoption and interoperability of frame relay technology among different vendors and carriers Frame Relay Forum was incorporated in May of 1991 as a non-profit organization. In April 2003, Frame Relay and MPLS forum merged into a new organization—MPLS & Frame Relay Alliance, which in April 2005 merged with the ATM Forum into a new organization currently known as the MFA Forum: www.mfaforum.org.

As it is known now: "The MFA Forum is an international, industry-wide, nonprofit association of telecommunications, networking, and other companies focused on advancing the deployment of multi-vendor, multi-service packet-based networks, associated applications, and interworking solutions. Through the efforts of the technical and marketing committees the forum encourages: (a) input to the development of standards throughout the various industry standards groups; (b) the creation of Specifications, based upon appropriate standards, on how to build and deliver MPLS, Frame Relay and ATM networks and services; (c) the definition of Interoperability test suites and coordination of Interoperability events to demonstrate the readiness of MPLS for network deployments; (d) the creation and delivery of educational programs to educate the industry about MPLS, Frame Relay and ATM technologies, services and solutions; and (e) building the awareness of MPLS as a technology ready for wide-scale deployment within service provider networks to deliver profitable services to the end-user community."

Some of the important specifications developed by what is known as the MFA Forum today include UNI (user-network interface), NNI (network-network interface), and FUNI (frame-based user-network interface). UNI/NNI interfaces define roles, transmission rates, service levels, and error recovery within the frame relay network. UNI defines interoperability between end points on the LAN and the end points of the frame relay network "cloud" (see Figure 1), whether NNI describes interconnection between frame relay network providers within the "cloud." In the mid-90s the original ATM Forum (MFA Forum now) had developed FUNI interworking specifications for ATM switches to frame relay devices offering packet delivery service that includes error detection, but not error correction—Greenstein (1995). It is also important to mention additional IWF (inter-working function) specifications developed by the Forum for connectivity between frame relay networks over ATM backbone. Additional information on ATM can be found in "ATM (Asynchronous Transfer Mode)."

Although, membership in the MFA Forum is required for access to specific programs or committees, a wealth of information is also available on their Web site for free and readers interested in frame relay, ATM, or MPLS technologies are strongly encouraged to use the MFA Forum Web site as a reference.

It is important to note, however, the MFA Forum does not develop standard specifications, but rather promotes and uses those specifications developed by the standard organizations, like ANSI, IEEE, IETF, ITU, and others.

ITU (International Telecommunications Union)

The ITU (www.itu.int) is part of the United Nations organization dealing with global telecommunications and service issues. ITU-T is a section within the ITU that was

created on March 1, 1993, replacing the former CCITT organization) whose origins go back to 1865. CCITT (or the ITU-T now) has a very long history designing and promoting different telecommunications standards, with frame relay being one of such standards.

Recommendations and reference information for different frame relay standards handled by the ITU-T can be found on their Web site. Following is a list of these recommendations:

- X.33: Access to packet-switched data transmission services via frame relaying data transmission services
- X.36: Interface between data terminal equipment (DTE) and data circuit-terminating equipment (DCE) for public data networks providing frame relay data
- X.37: Encapsulation in X.25 packets of various protocols including frame relay
- X.76: Network-to-network interface between public networks providing PVC and/or SVC frame relay data transmission service
- X.78: Interworking procedures between networks providing frame relay data transmission services via B-ISDN
- X.84: Support of frame relay services over MPLS core networks
- X.111: Principles for the routing of international frame relay traffic
- X.124: Arrangements for the interworking of the E.164 and X.121 numbering plans for frame relay and ATM networks
- X.125: Procedure for the notification of the assignment of international network identification codes for public frame relay data networks and ATM networks numbered under the E.164 numbering plan
- X.142: Quality of service metrics for characterizing frame relay /ATM service interworking performance
- X.144: User information transfer performance parameters for public frame relay data networks
- X.145: Connection establishment and dis-engagement performance parameters for public frame relay data networks providing SVC services
- X.146: Performance objectives and quality of service classes applicable to frame relay
- X.147: Frame relay network availability
- X.148: Procedures for the measurement of the performance of public data networks providing the international frame relay service
- X.149: Performance of IP networks when supported by public frame relay data networks
- X.151: Frame relay operations and maintenance—principles and functions
- X.272: Data compression and privacy over frame relay networks
- X.328: General arrangements for interworking between public data networks providing frame relay data transmission services and integrated services digital networks (ISDNs) for the provision of data transmission services
- X.329: General arrangements for interworking between networks providing frame relay data transmission services and B-ISDN

IETF RFCs

Important standardization work for frame relay was also done by the IETF that also developed several RFCs for frame relay networks:

- RFC 1293*: Inverse Address Resolution Protocol (January 1992).
- RFC 1586*: Guidelines for running OSPF over frame relay networks (March 1994).
- RFC 1973*: PPP in frame relay (June 1996)
- RFC 2115*: Management information base for frame relay DTEs using SMIV2 (September 1997).
- RFC 2427*: Multiprotocol interconnect over frame relay (September 1998).
- RFC 2590*: Transmission of IPv6 packets over frame relay networks (May 1999).
- RFC 2954*: Definitions of managed objects for frame relay service (October 2000).
- RFC 2955*: Definitions of managed objects for monitoring and controlling the frame relay/ATM PVC service interworking function (October 2000).
- RFC 3020*: Definitions of managed objects for monitoring and controlling the UNI/NNI multilink frame relay function (December 2000).
- RFC 3034*: Use of label switching on frame relay networks specification (January 2001).
- RFC 3070*: Layer two tunneling protocol (L2TP) over frame relay (February 2001).
- RFC 3133*: Terminology for frame relay benchmarking (June 2001).
- RFC 3202*: Definitions of managed objects for frame relay service level definitions (January 2002).

In the section of this chapter dedicated to network management we will provide additional details on frame relay MIBs (RFC 2115 its predecessor 1315, 2954, 2955, 3020, and 3202). And in another section on frame relay in enterprise networks we will focus on one of the more important standards multiprotocol interconnects (RFC 2427 and its predecessors RFC 1294 and ARFC 1490) that played a significant role in transferring mission critical enterprise legacy protocols over frame relay WAN.

NETWORK MANAGEMENT Troubleshooting

To get a practical perspective on frame relay network design and management techniques let's start with a description of the equipment, physical, and logical circuits comprising any frame relay network. Probably the most important devices at the heart of a frame relay network are the so-called FRADs (frame relay assembler/disassembler)—networking equipment that assembles and disassembles data frames. In fact, many networking devices that encapsulate other protocols into frame relay protocol are FRADs, that is, routers/switches encapsulating Ethernet, TCP/IP protocol, legacy protocols, and so on and performing frame assembly/disassembly are indeed FRADs. The same is true for devices performing

encoding and encapsulation of voice and video streams into frame relay. Although, as we mentioned earlier, as a result of the nonhomogenous and bursty nature of frame relay networks, neither voice nor video implementation over frame relay became popular; occasionally we may still find such implementations here and there.

Because frame relay is a connection-oriented end-to-end protocol at any given point in time in a frame relay network, connections (or virtual circuits) exist between pair of devices utilizing the network. These virtual circuits provide bidirectional communications paths and are uniquely identified by DLCIs. Because multiple virtual circuits can be multiplexed over a single physical circuit, both network complexity and costs are significantly reduced in comparison with dedicated leased lines. And it's also very important to keep in mind the multiplexing logical over physical circuits capability of frame relay networks as well as the fact that a virtual circuit in frame relay network can pass through a large number of intermediate network switches. Thus, correlation between virtual circuits and their physical paths is extremely important for designing, managing, and troubleshooting the network.

One additional notable comment: originally designed as an end-to-end network topology, in the mid-1990s many frame relay networks had migrated to an ATM core further converting to MPLS in the late 1990s. And as was mentioned earlier, the MFA Forum played a very important role in enabling this transformation process by leading the effort and defining the UNI/NNI and NNI/NNI specifications for frame relay to ATM and frame relay to MPLS conversions.

There are two types of virtual circuits in frame relay networks: SVC (switched virtual circuit) and PVC (permanent virtual circuits).

An SVC is a temporary connection used when only sporadic data transfer between frame relay devices is required. SVC sessions consist of the following four states:

- **Call setup**—virtual circuit between two frame relay devices is established.
- **Data transfer**—data is actively being transferred between the devices.
- **Idle**—connection is active, but no actual data is being transferred. Typically, when the SVC stays idle a predefined period of time, the circuit will be terminated.
- **Call termination**—virtual circuit is being terminated.

A new SVC has to be created in order to transfer data after a virtual circuit has been terminated. Because frame relay was developed as part of BISDN standard setup, maintenance, and termination of SVC utilizes the same signaling protocols as defined in BISDN. It's important to note, though, that implementation of SVCs in frame relay network is very limited as most networks are using PVCs (permanent virtual circuits).

Contrary to SVCs, PVCs are permanently established connections used for frequent and consistent data transfers between devices across the frame relay network. Therefore, call setup and termination would only occur when a DLCI comes up or brought down either explicitly

or because of restart as a result of error recovery circuit setup and termination. Hence, a PVC can only operate in one of the two following states:

- **Data transfer**—data is actively being transferred between the devices.
- **Idle**—connection is active, but no actual data is being transferred.

Because PVCs constitute permanent connections the virtual circuit will not be terminated regardless how long it was in an idle state.

One of the inherent mechanisms for examining and enforcing reliability of a frame relay network is the CRC algorithm used in FCS of frame relay packets. The CRC compares the calculated value with the value included in the FCS part of the frame to determine whether an error occurred during the transmission.

Let's describe some typical situations and techniques for troubleshooting frame relay connections. For purposes of description, let's use the terminology and examples from a popular frame relay device—Cisco router. Below are the different statuses a frame relay connection may be presented on a Cisco device:

- Both interface and line protocol are down: typically points to a physical connectivity problem. The first and simplest troubleshooting procedure at this point is testing the connection in a loopback mode.
- Interface is up while line protocol is down: at this point the router is receiving carrier signal from the CSU/DSU or modem. However, there is a problem with frame relay configuration settings. Make sure the carrier has activated their port and that the LMI settings match. Next step would be performing circuit integrity testing by using loopback tests at different points all the way from the port on the local device to the port on carrier's frame relay equipment. Another typical problem that may cause this situation is misconfiguration of DLCI numbers.
- Both the interface and line protocol are up: this typically means a reliable frame relay connection has been established. It's important to note that keepalive messages are necessary for frame relay networks, as this is the means for local frame relay devices to know which DLCIs have been provisioned.
- Using the debug mechanism on Cisco's equipment is a good way to monitor frame relay connections. Not as with other instances of using the debug function "*debug frame-relay lmi*" generates few messages only and is a good troubleshooting technique that can provide an answer to the following important questions:
 - Are we receiving full LMI status messages for the PVCs from the carrier?
 - Are the DLCIs correct?
 - Is the other end of the PVC up or down?

Problem Determination

Let's continue with more comprehensive problem determination scenario using our example of Cisco routers that can be used both as FRADs as well as carriers' frame relay

switches. First, it's important to setup the keepalive on frame relay switches higher than it is on the FRADs. For problem determination, the following commands can be issued:

- On FRADs:
 - show interface serial0* and/or *show frame-relay lmi* - confirming LMI is exchanged
 - show frame-relay pvc*—to check if FRAD knows about PVC
 - show frame-relay map*—to confirm DLCI is mapped to IP
- On the frame relay switch:
 - show frame-relay route*—to check how frames are switched

Designers of the frame relay had included multiple provisioning for network management and problem determination. Following are some the status information exchanges included in frame relay networks:

Link integrity verification timer: specifies how frequently the FRAD initiates a status inquiry message. The valid values are between 5 to 30 seconds, with the default value of 10 seconds.

Status information: is a standard inquiry from a frame relay device performed every time the link integrity verification timer expires. The status inquiry returns status information about the network. Also, by sending such inquiries the FRAD is confirming to the frame relay carrier equipment that it is in service. If a status inquiry is not sent, the network will generate an alarm.

Full status inquiry: also returns all of the active DLCI numbers. Its frequency ranges from 1 to 255, meaning full status inquiry will be the only inquiry sent by the FRAD (value = 1) or on each 254 status information inquiries one full status inquiry is sent (value-255). The default value is 6, which means the user equipment sends 5 regular status inquiries, then the full status inquiry.

Management Tools

A vast majority of the standard SNMP-based management tools have good interfaces for managing frame relay networks. Frame relay MIBs provide information that allows standard network management tools to obtain performance information, monitor status and configuration information. The MIB allows not just monitoring, but also implementation of certain operational and configuration commands: that is, adding, deleting, or modifying PVCs, turning selected PVCs on or off, and so on. Based on SNMP information received from different parts and devices in the frame relay network, a management tool can also obtain a detailed status of internal elements of the network, although not necessarily from the frame relay MIBs: that is, network cards and ports, routing tables, and so on (Stallings, 1997).

SNMP information can be obtained by issuing SNMP poll commands or from traps generated by the SNMP agents. Frame relay status inquiry information

described in the previous section can also be obtained through SNMP polling. And because frame relay networks are typically shared between different service subscribers the MIBs support granularity necessary to provide only access to the relevant parts of the network, such as interfaces and PVCs to the eligible parties.

SNMP enables network management tools to gather important information from the frame relay MIBs that are composed of three groups. Samples of information obtained from frame relay networks by SNMP management tools include:

- Group for DLCI management interface offers port statistics, such as:
 - Signaling state
 - Signaling state downtime
 - Port unavailable time
- Group describing the circuits offers PVC statistics
 - Throughput (Tx/Rx, max/average)
 - Utilization (Tx/Rx, max/average)
 - Frame relay network delay (max/average)
- Group describing the errors

SUMMARY

Frame Relay—Current Status

In general, frame relay networks are provisioned by carriers (or service providers) offering services to different end users—that is, public frame relay service, whereas so-called private frame relay networks are deployed and maintained by enterprises. The vast majority of frame relay networks are public networks, whereas carriers' infrastructure and equipment is essentially shared by several end users. However, several typically large enterprises had also deployed private frame relay networks, where they own and maintain not just the peripheral equipment connecting to the frame relay "cloud" but also the "cloud" itself. In some cases private frame relay networks are also being implemented on "shared" equipment owned by an ISP. The SLA given by the service providers in such cases today is their commitment to map the PVC in the network core over exclusive LSPs (label switched paths). Additional information about label switching can be provided in Chapter 92 dedicated to MPLS.

In the mid-1990s, market researcher Vertical Systems Group (Dedham, MA) predicted sales of frame relay access equipment to more than triple in the next three years from \$171.8 million in 1995 to \$613.4 million by 1998 (Rabinovitch, 1996). Obviously, given recent developments in WAN technologies, such a trend was not expected to continue. On the contrary, many market pundits predicted that frame relay was going to be displaced by the ATM technology. Surprisingly enough, frame relay technology proved to be so reliable and cost effective that this transition to ATM never really happened. And despite the fact users are migrating to newer technologies and the vast majority of new installations today are using MPLS or even Metro Ethernet, the total number of frame relay ports installed almost did not change and was estimated

at more than 2 million ports in 2005, generating revenue in excess of \$16B for the carriers.

The emerging trend, especially for public frame relay networks, is to migrate to so-called “hybrid” networks, where end-users are still using frame relay PVC connections, but instead of going end-to-end on a frame relay “cloud,” frame relay PVCs are terminated in carriers’ point of presence from where it’s being carried over an MPLS network. In addition to new application requirements, such as voice over IP, video, and other multimedia applications requiring QoS differentiation cost is another major driver for migration from pure frame relay networks to MPLS networks. Because frame relay services are being priced according to the CIR and distance, long-haul PVCs are typically the first candidates for migration. And work performed by the MFA Forum described in the section above, assures smooth migration path to the newer technologies. In fact, migration of the core of the network to MPLS (with the PVCs terminating at the edge) had actually started in the early 2000s, when the major carriers started converging their dissimilar networks onto a single core topology, predominantly MPLS.

Enterprise Perspective

Popularity of frame relay networks in the 1990s introduced a new alternative for legacy network transport facilities in the form of multiprotocol interconnect over frame relay standard—RFC 2427. This standard allows transport of multiple protocols over the same access line and even the same DLCI. Although access devices allow separate queues for different protocols and a protocol-level prioritization scheme within the frame relay cloud, there are no provisions for legacy protocol prioritization. RFC 2427 supports protocol mixing for a single DLCI, in most implementations mission-critical legacy traffic is being separated from the less critical traffic on different DLCIs, with a higher CIR. So enterprises using frame relay networks for multiprotocol consolidation are always taking precautions to isolate mission-critical traffic from less critical applications.

Because of difference in behavior of different high-level protocols (i.e., legacy SNA and TCP/IP) as described in the section about Performance and Congestion Control above, “considerate” legacy SNA applications are reacting to mild congestions in frame relay networks by modifying the window size. “Inconsiderate” TCP/IP applications typically ignore mild congestion, instead increasing TCP window-size, and only reacting to severe congestion by eventually discarding frames (Lynch, Gray, and Rabinovitch, 1997). Therefore, capacity planning in a consolidated multiprotocol frame relay network becomes a challenging task sometimes resulting in over-provisioning.

Service Providers Perspective

Even though frame relay services are not as popular as they were a few years ago mainly because MPLS VPNs and even Metro Ethernet services are available in more and more places now, carriers are still offering frame relay services for new installations. Obviously, from a

financial standpoint, it makes a lot of sense for service providers, because their edge frame switches are already depreciated, thus they can offer new circuits with minimal implementation costs, so the resulting revenues consist of almost pure profits. It’s also important to mention, that if the original specifications for frame relay access were in the 56kbps to T1/E1 speed range, subsequently, T3/E3 speeds for frame relay access became available too. And in December of 1998, the Frame Relay Forum (now MFA Forum) ratified “Physical Layer Interface Implementation Agreement” FRF.14 for introducing support of OC3 and even OC12 access to frame relay services.

As was shown above frame relay remains an important source of revenue for service providers. However, with growing customer demand to accommodate multi-protocol and emerging multimedia applications at lower price points carriers are increasingly looking at deploying new but already proven technologies, such as MPLS VPNs or Metro Ethernet. Many carriers are already deploying both Metro Ethernet and MPLS VPN technologies in different locations all over the world, including North America, Europe, Central America, and Asia. In the United States, Metro Ethernet services are available not only from the major carriers but also the cable companies. An even a more important technology for WAN heavily lobbied by service providers is MPLS. Both MPLS tunneling (or MPLS at layer 2) and MPLS VPN (or MPLS at layer 3) are being aggressively pursued by service providers. Hybrid networks are integrating frame relay access with MPLS network cores, where DLCIs are being mapped to MPLS LSPs. Because MPLS tunneling is by nature a multiprotocol technology, it can natively support both IP and legacy traffic. The fact customers can still use their existing frame relay equipment while migrating to a hybrid network environment would also make such migration projects more affordable. And service providers can continue to support frame relay services while expanding their core infrastructure and positioning themselves for new Metro Ethernet and MPLS offerings.

CONCLUSION

Frame relay technology has been optimized for statistical multiplexing providing the same bandwidth-sharing and efficiency as its predecessor X.25. Statistical multiplexing means that no bandwidth is allocated to virtual circuits until actual data needs to be transmitted. Then, the bandwidth within the network is dynamically allocated on a frame-by-frame basis. If, for a short period of time, more data needs to be transmitted than the transmission facilities can accommodate, the switches within the network will buffer the data for later transmission. If this over-subscription persists, congestion control mechanisms are invoked.

Frame relay was developed based on experience gained from X.25, and took into account the modern digital physical network infrastructure, which became much more resilient and reliable. In comparison with X.25, frame relay eliminates much of the protocol processing done by the network, thereby reducing the portion of the transmission latency attributed to this processing. This

simplification of the protocol is based on elimination of error recovery functions, utilizing functionality in the ingress and egress points of the network to guarantee error-free end-to-end transfer of frames. This protocol processing, which is still necessary to guarantee reliable data delivery is left to the higher layers of the OSI reference model implemented by the endpoint devices.

Frame relay interface specifications provide both signaling and data transfer mechanisms between endpoints and the network. This interface allows communication bandwidth to be shared among multiple users, creating instantaneous bandwidth allocation on demand. Each frame contains header information that is used to determine the routing of the data to the desired destination. This enables each endpoint to communicate with multiple destinations via a single access link to the network. Instead of fixed amounts of bandwidth allocated to the resource, frame relay traffic receives full bandwidth for short transaction bursts.

Let's briefly reiterate the main benefits of frame relay networks:

- Reduced internetworking costs,
- Increased performance with reduced network complexity, and
- Increased interoperability via international standards.

Reduced internetworking costs: when using a private frame relay network, statistically multiplexed traffic from multiple sources over private backbone networks can reduce the number of circuits and corresponding cost of bandwidth in the WAN. And public frame relay services always offer cost savings, when compared with the equivalent services over dedicated leased lines. Because frame relay provides multiple logical connections over a single physical connection, access costs are also reduced. Additionally, equipment costs may be lowered by reducing the number of ports required to access the network. For remote access devices, access line charges can also be lowered by reducing the number of physical circuits needed to reach the networks.

Increased performance with reduced network complexity: by reducing the amount of processing in comparison to X.25, and by efficiently utilizing high-speed digital transmission lines, frame relay can improve performance and response times of applications. Frame relay also reduces the complexity of the physical network without disrupting higher level network functions. In fact, it actually utilizes the existence of these higher layer protocols to its advantage. Frame relay also provides a common network transport for multiple traffic types while maintaining transparency to higher level protocols unique to the individual traffic types. Addressing information contained in the network frames enables the network to route them to the proper destination.

Increased interoperability via international standards: Frame relay is a well-established protocol accepted by networking vendors and service providers. Simplicity of the frame relay protocol accommodates quick and easy interoperability testing procedures between devices from different vendors, and the MFA Forum sponsors

interoperability testing among different equipment manufacturers as well as between the different protocols it is responsible for: that is, frame relay, ATM, and MPLS.

Some industry pundits have labeled frame relay as an "interim technology." As a matter of fact, any technology is "interim," providing a basis for a better and improved technology in the future. The important question, however, is how long the "interim" technology will survive and is it going to offer return on investment? Obviously, based on the status of frame relay technology for over more than a decade, and its positioning today both by enterprises and service providers, frame relay is indeed a very interesting and successful "interim" technology that offered sizeable return on investment. Frame relay proved to be a reliable and cost-effective solution for WAN from the 1990s until today.

ACKNOWLEDGMENT

I would like to thank all the reviewers for their comments and suggestions that helped to improve this chapter making it more interesting and comprehensive. Especial thanks goes to a long time friend and colleague Robert Downing of IP Infusion, former President of the Frame Relay Forum, for his valuable feedback and remarks.

GLOSSARY

BECN: Backward explicit congestion notification is a header bit transmitted by the destination terminal requesting that the source terminal send data more slowly.

CIR: Committed information rate is bandwidth (in bits per second) associated with a logical connection in a permanent virtual circuit—see PVC.

DE: Discard eligibility is a header bit signifying the frame was sent above the CIR and, thus, is eligible for discard during network congestions.

DLCI: Data link connection identifier is a multipart field that identifies virtual channel mapping onto the physical channel.

FECN: Forward explicit congestion notification is a header bit transmitted by the source (sending) terminal requesting that the destination (receiving) terminal slow down its requests for data.

FRAD: Frame relay assembler/disassembler also sometimes referred to as frame relay access device is a box that encapsulates data packets and decapsulates (removes frame relay headers and trailers from) incoming packets.

Frame Relay Forum: Now part of the MFA (MPLS-Frame Relay-ATM) Forum is an international, industry-wide, nonprofit association of telecommunications, networking, and other companies focused on advancing the deployment of multi-vendor, multi-service packet-based networks, associated applications, and interworking solutions.

LMI: Local management interface is a set of enhancements to the basic frame relay specification often called extensions. Key LMI extensions include global addressing, virtual circuit status messages, and multicasting.

MIB for frame relay: (also see RFC 2115) Defines a portion of the management information base (MIB) for use with network management protocols in SNMP managed networks, which defines objects for managing frame relay interfaces on DTEs.

Multiprotocol over frame relay: (also see RFC 2427) Is a standard that allows transport of multiple protocols over the same access line and even the same DLCI. Although access devices allow separate queues for different protocols and a protocol-level prioritization scheme within the frame relay cloud there are no provisions for legacy protocol prioritization. RFC 2427 supports protocol mixing for a single DLCI, in most implementations mission-critical legacy traffic is being separated from the less critical traffic on different DLCIs, with a higher CIR.

PVC: Permanent virtual circuit is a software-defined logical connection in a frame relay network.

RFC 2115: (also see MIB for frame relay) Defines a portion of the management information base (MIB) for use with network management protocols in SNMP managed networks, which defines objects for managing frame relay interfaces on DTEs.

RFC 2427: (also see multiprotocol over frame relay) Is a standard that allows transport of multiple protocols over the same access line and even the same DLCI. Although access devices allow separate queues for different protocols and a protocol-level prioritization scheme within the frame relay cloud there are no provisions for legacy protocol prioritization. RFC 2427 supports protocol mixing for a single DLCI, in most implementations mission-critical legacy traffic is being separated from the less critical traffic on different DLCIs, with a higher CIR.

Split horizon: Is a method of preventing a routing loop in a network, whereby the information about routing for a particular frame is never sent back in the direction from which it was received.

SVC: Switched virtual circuit is a temporary virtual circuit that is established and maintained only for the duration of a data transfer session.

INTRODUCTION

The purpose of this chapter is to introduce the reader to the basic aspects of asynchronous transfer mode (ATM) networks. The length of this short chapter makes it impossible to cover all important aspects of ATM networks. Much of the material in this chapter is based on existing tutorials on ATM, including www.iec.org/online/tutorials/atm_fund/index.html, www.telecomspace.com/vop-atm.html, www.npac.syr.edu/users/maresh/homepage/atm_tutorial/final.pdf, www.mfaforum.org/education/downloads/CDNwhtpapr.Vid.Final.pdf, www.coming.com/docs/opticalfiber/IEC%20FTTH%20101%20Tutorialv2.pdf, McDysan and Spohn (1999), Vetter (1995), Sackett and Metz (1997), Ibe (2001), Dobrowski and Grise (2001). The industrial momentum behind ATM technology and the intensive research interest in ATM has led to a vast and diversified literature in recent years. Most of the cited references are mainly review articles or documents of ATM and MFA Forums. Readers interested in further understanding of the individual topics are referred to the corresponding papers and the references therein.

Basic Principles

Various network applications are requiring increasingly higher bandwidth and generating a heterogeneous mix of network traffic. Existing networks cannot provide the transport facilities to efficiently support a diversity of traffic with various service requirements. ATM was designed to be potentially capable of supporting heterogeneous traffic (e.g., voice, video, data) in one transmission and switching fabric technology. It promised to provide greater integration of capabilities and services, more flexible access to the network, and more efficient and economical service.

ATM is a switching and multiplexing technology that employs small, fixed-length packets (called cells). Each cell

has 5 bytes of header information and a 48-byte information field (payload). The reason for choosing a fixed-size packet was to ensure that the switching and multiplexing function could be carried out quickly, easily, and with least delay variation. The reason for choosing a small size cell was mainly a result of the need to support delay-intolerant interactive voice service (e.g., phone calls) with a small packetization delay, i.e., the time needed to fill a cell with PCM (pulse code modulation) encoded voice samples arriving at the rate of 64 Kbps.

ATM is a connection-oriented technology in the sense that before two systems on the network can communicate, they should inform all intermediate switches about their service requirements and traffic parameters. This is similar to the telephone networks where a fixed path is set up from the calling party to the receiving party. In ATM networks, each connection is called a virtual circuit or virtual channel (VC), because it also allows the capacity of each link to be shared by connections using that link on a demand basis rather than by fixed allocations. The connections allow the network to guarantee the quality of service (QoS) by limiting the number of VCs. Typically, a user declares key service requirements at the time of connection setup, declares the traffic parameters, and may agree to control these parameters dynamically as demanded by the network.

ATM was intended to provide a single unified networking standard that could support both synchronous and asynchronous technologies and services, while offering multiple levels of quality of service for packet traffic.

ATM sought to resolve the conflict between circuit-switched networks and packet-switched networks by mapping both bit streams and packet streams onto a stream of small fixed-size “cells” tagged with virtual circuit identifiers. Cells are typically sent on demand within a synchronous time slot pattern in a synchronous bit stream: what is asynchronous here is the sending of the cells, not the low-level bitstream that carries them.

In its original conception, ATM was to be the enabling technology of the “broadband integrated services digital network” (B-ISDN) that would replace the existing narrowband “integrated services digital network (ISDN). The full suite of ATM standards provides definitions for layer 1 (physical connections), layer 2 (data link layer), and layer 3 (network) of the classical OSI seven-layer networking model. Because ATM is asynchronous, it provides true bandwidth-on-demand. Additionally, ATM is capable of handling any form of information (e.g., data, voice, video, audio, e-mail, faxes), moving this information quickly across a network with millions of virtual paths and channels between end-user equipment.

ATM allows the user to select the required level of service, provides guaranteed service quality, and makes reservations and preplans routes so those transmissions needing the most attention are given the best service.

The MFA Forum, ITU, and ANSI

With the objective of accelerating the convergence of standards and industry cooperation, an international consortium called the ATM Forum was founded to ensure interoperability between public and private ATM implementations and to promote the use of ATM products and services. Although it was not a standard body, the ATM Forum worked closely with standard organizations such as the International Telecommunications Union (ITU) and Internet Engineering Task Force (IETF) in developing the definitions for ATM standards. In 2005 the ATM Forum was merged in MPLS Frame Relay and ATM Forum—MFA Forum, which is an international, industry-wide, nonprofit association of telecommunications, networking, and other companies focused on advancing the deployment of multi-vendor, multi-service packet-based networks, associated applications, and interworking solutions.

The ITU is rooted in the International Telegraphy Union, founded in Paris in 1865. Its name changed in 1934, and in 1947 the ITU became an agency of the United Nations. The ITU works with public and private organizations to develop earth-linked and satellite communications, while developing standards for all types of telecommunication technology.

The ITU-Telecommunication Standardization Sector (ITU-T) is the leader in defining integrated services digital network (ISDN), B-ISDN, and ATM specifications. The American National Standards Institute (ANSI) is the formal standards body guiding the development of ATM in the United States.

New Developments

Numerous telcos have implemented wide-area ATM networks, and many ADSL implementations use ATM. However, ATM has failed to gain wide use as a LAN technology, and its great complexity has held back its full deployment as the single integrating network technology in the way that its inventors originally intended.

Many people, particularly in the Internet protocol-design community, considered this vision to be mistaken. Although there is a need for a unifying protocol at network layer, to be able to run over all existing and

future link-layer technologies, ATM could not do this role. Conveniently, IP already plays the role of such an integrator in a more scalable, more flexible, less complex, and most importantly, less expensive way than ATM could do. Therefore, there was no point in implementing ATM as an integrator at the network layer.

In addition, the need for cells to reduce jitter has disappeared as transport speeds increased (see below), and improvements in voice over IP have made the integration of speech and data possible at the IP layer, again removing the incentive for ubiquitous deployment of ATM. Most telcos are now planning to integrate their voice network activities into their IP networks, rather than their IP networks into the voice infrastructure.

Many technically sound ideas from ATM were adopted by MPLS, a generic layer 2 packet switching protocol. ATM remains widely deployed, and is used as a multiplexing service in DSL networks, where its compromises fit DSL’s low-data-rate needs well. In turn, DSL networks support IP (and IP services such as VoIP) via PPP over ATM.

ATM will remain deployed for some time in higher-speed interconnects where carriers have already committed themselves to existing ATM deployments; ATM is used here as a way of unifying PDH/SDH traffic and packet-switched traffic under a single infrastructure.

However, ATM is increasingly challenged by speed and traffic shaping requirements of converged networks. In particular, the complexity of SAR imposes a performance bottleneck, as the fastest SARs known run at 2.5 Gbps and have limited traffic shaping capabilities.

Currently it seems like Ethernet implementations (10-Gbit-Ethernet, Metro Ethernet) will replace ATM in many locations (<http://standards.ieee.org/catalog/olis/lanman.html>, www.metroethernetforum.org).

ATM PROTOCOL REFERENCE MODEL

The ATM protocol reference model is based on standards developed by the ITU. Communication from higher layers is adapted to the lower ATM defined layers, which in turn pass the information onto the physical layer for transmission over a selected physical medium. The protocol reference model is divided into three layers: the ATM adaptation layer (AAL), the ATM layer, and the physical layer, as shown in Figure 1. The three management planes—user/control plane, layer management and plane management, are shown in Figure 2.

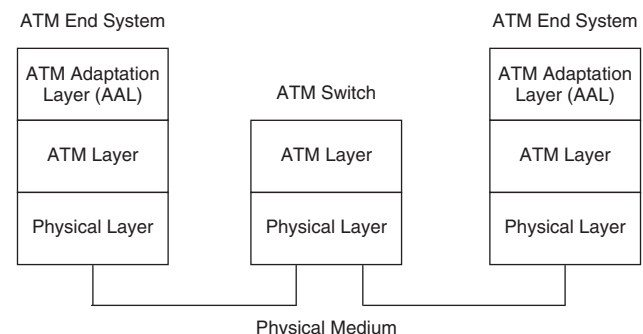

Figure 1: ATM protocol structure

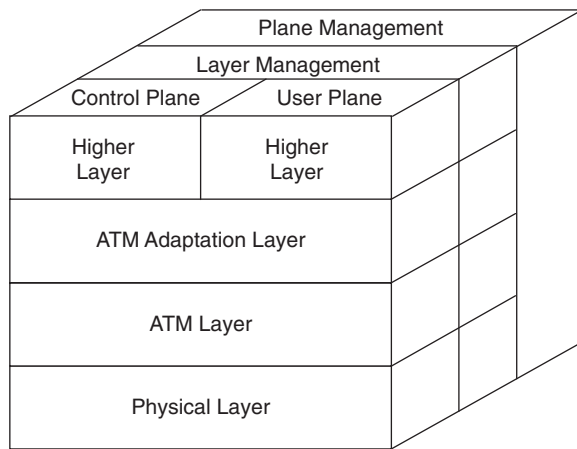

Figure 2: ATM model

The ATM Adaptation Layer

The ATM adaptation layer (AAL) interfaces the higher layer protocols to the ATM layer. It relays ATM cells both from the upper layers to the ATM layer and vice versa. When relaying information received from the higher layers to the ATM layer, the AAL segments the data into ATM cells. When relaying information received from the ATM layer to the higher layers, the AAL must take the cells and reassemble the payloads into a format that the higher layers can understand. This is called segmentation and reassembly (SAR).

Four types of AALs were proposed, each supporting a different type of traffic or service expected to be used on ATM networks. The service classes and the corresponding types of AALs are as follows:

- **AAL0:** AAL0 payload consists of 48 bytes without special field, is also referred to as raw cells.
- **AAL1:** AAL1 was designed to support constant bit rate applications. Examples of these types of applications include 64 Kbps voice, fixed-rate uncompressed video, and leased lines for private data networks.
- **AAL2:** AAL2 was initially conceived to support variable bit rate applications that require a bounded delay for delivery. One example of such applications is compressed packetized voice or video. The requirement on bounded delay for delivery is necessary for the receiver to reconstruct the original uncompressed voice or video. Although, AAL2 was conceived in early years of ATM development, it was not designed. So later when ATM designers needed an AAL for voice traffic, they first labeled it AAL6 and then quickly relabeled it as AAL2. So today, AAL2 is used for carrying voice traffic and allows several small compressed voice packets to be packed in a single 48-byte cell payload.
- **AAL3/4:** AAL3 and AAL4 were conceived for connection-oriented and connectionless data traffic that do not have delay constraints. Both these were to support variable bit rate data applications such as file transfer. However, designers quickly realized that there was little difference between the two types of traffic and so a single AAL called AAL 3/4 was designed. Because of the high

complexity of AAL3/4 protocols, a simpler AAL called AAL5 was later proposed and is the common AAL used today. AAL 3/4 is no longer used.

- **AAL5:** AAL5 is designed for data traffic that do not have delay constraints. Examples of applications include IP traffic, LAN, FTP, and network management.

Although each AAL is optimized for a specific type of traffic, there is no stipulation in the standards that AALs designed for one class of traffic cannot be used for another. In fact, many vendors of ATM equipment currently manufacture products that use AAL5 to support all the above classes of traffic, and most activities at the ATM Forum were focused on AAL5. The AAL5 is also important in the internetworking of different networks and services. For more discussion on the issues in AAL5 design, see Suzuki (1994). AAL1 is also important, because it is used for streams and for circuit emulation (www.mfaforum.org/ftp/pub/approved-specs/af-arch-0204.000.pdf).

AAL5 places control information in an 8-octet trailer at the end of the packet. The AAL5 trailer contains a 16-bit length field, a 32-bit cyclic redundancy check (CRC) and two 8-bit fields labeled UU and CPI that are currently unused.

In AAL5, each higher layer packet is divided into an integral number of ATM cells. At the receiving end, these cells are reassembled into a packet before delivery to the receiving host. The last cell contains padding to ensure that the entire AAL5 protocol data unit (PDU) is a multiple of 48 octets long. The final cell contains up to 40 octets of data, followed by zero padding and the 8-octet trailer.

The ATM Layer

The ATM layer provides an interface between the AAL and the physical layer. This layer is responsible for relaying cells from the AAL to the physical layer for transmission and from the physical layer to the AAL for use at the end systems. When it is inside an end system, the ATM layer receives a stream of cells from the physical layer and transmits cells with new data. When it is inside a switch, the ATM layer determines where the incoming cells should be forwarded to, modifies the corresponding connection identifiers, and forwards the cells to the next link. Moreover, it buffers incoming and outgoing cells, and handles various traffic management functions such as cell loss priority marking, congestion indication, and generic flow control. It also monitors the transmission rate and conformance to the service contract (traffic policing). Traffic management was a hotly debated topic in the ATM Forum, and we shall address the important issues in more details later.

The fields in the ATM cell header define the functionality of the ATM layer. The format of the header for ATM cells has two different forms, one for use at the user-to-network interface (UNI) and the other for use internal to the network, the network-to-node interface (NNI), as shown in Figure 3 (www.mfaforum.org/ftp/pub/approved-specs/afarch-0193.000.pdf, www.mfaforum.org/ftp/pub/approved-specs/af-sig-0061.001.pdf). ATM user network interface (UNI) signaling specification version 4.1 was standardized in 2002. At the UNI, the header dedicates four bits to a function called generic flow control (GFC), which was originally designed to control the amount of

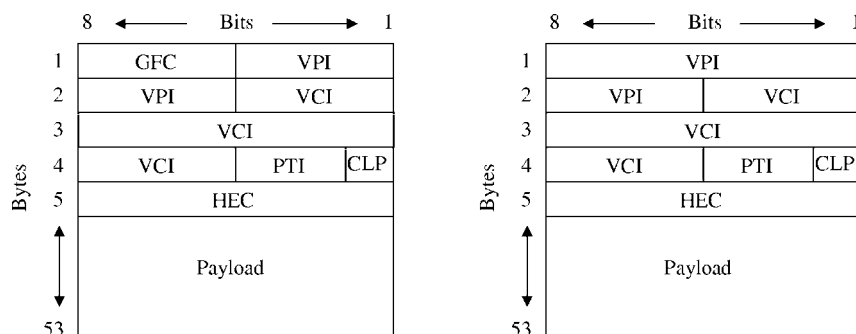

Figure 3: UNI (left) and NNI (right) ATM cell format

traffic entering the network. This allows the UNI to limit the amount of data entering the network during periods of congestion. At the NNI, these four bits are allocated to the virtual path identifier (VPI).

The ATM inter network interface (AINI) protocol was designed for use between ATM networks. AINI protocol is based on ATM Forum PNNI signaling (www.mfaforum.org/ftp/pub/approved-specs-af-cs-0125.002.pdf, www.mfaforum.org/ftp/pub/approved-specs-af-pnni-0055.001.pdf). The networks on either side of the AINI may be running any protocol internally. However, the goal in defining this protocol was to facilitate interworking of two networks running PNNI internally in disjoint PNNI routing domains.

Figure 4 gives an illustration of ATM network interfaces.

The VPI and the virtual channel identifier (VCI) together, as shown in Figure 5, form the routing field, which associates each cell with a particular channel or circuit, see Figure 6. Each VCI identifies a single flow (channel); the VPI allows grouping of VCs with different VCIs that can be switched together as an entity. However, the VPIs and VCIs have significance only on the local link; the contents

of the routing field will generally change as the cell traverses from link to link. For the UNI, the routing field contains 24 bits and thus the interface can support over 16 million concurrent sessions. At the NNI, the field contains 28 bits, allowing for over 268 million sessions to share a link within a subnet. We refer the readers to the discussion of important issues in private network-to-network interface (PNNI) routing to www.mfaforum.org/ftp/pub/approved-specs-af-pnni-0055.001.pdf and Lee (1995).

The payload type indicator (PTI) field is used to distinguish between cells carrying user data and cells containing control information. This allows control and signaling data to be transmitted on a different subchannel from user data and hence separation of user and control data. A particular bit is used by the AAL if the cell is a part of an AAL5 connection. Another bit is used to indicate that the cell has experienced congestion.

The cell loss priority (CLP) bit provides the network with a selective discard capability within each VPI/VCI. Cells with a CLP bit setting of 1 are discarded before cells with a CLP bit setting of 0. This bit could be set by a user to indicate lower-priority cells that could be discarded by the

Figure 4: ATM network interfaces

Figure 5: Virtual path and virtual channels

Figure 6: VP and VC switching

network during periods of congestion. Whereas data applications generally cannot suffer any cell loss without the need for retransmission, voice and video traffic, especially if not compressed, can tolerate minor cell loss. One could, therefore, code voice and video traffic such that some less important cells could be marked with CLP = 1 while other more important cells would be marked with CLP = 0. The CLP bit could also be used by the network to indicate cells that exceed the negotiated rate limit of a user.

The header error check (HEC) field is used to reduce errors in the header that cause a misrouting of the cell for one user into another user's data stream. This field contains the result of an 8-bit CRC checking on the ATM header (this does not include the payload). When a switch or an end system terminates the header, multiple-bit errors will be detected with a high probability. Moreover, a single-bit error can be corrected. This is desirable since ATM is intended for use on fiber optics link, where the error rate is less than 10^{-9} with current modulation techniques. Therefore, single-bit error correction is quite effective in removing most header errors.

The Physical Layer

The physical layer defines the bit timing and other characteristics for encoding and decoding the data into suitable electrical/optical waveforms for transmission and reception on the specific physical media used. In addition, it also provides cell delineation function, header error check (HEC) generation and processing, performance monitoring, and payload rate matching of the different transport formats used at this layer.

The Synchronous Optical Network (SONET), a synchronous transmission structure, is often used for framing and synchronization at the physical layer. In addition to the optical media and line rates defined for SONET, the ATM Forum has proposed a variety of physical layer standards, such as ATM over twisted-pair wire. This will accelerate the acceptance of ATM as a desktop connection technology since existing cabling plants can be retained and the cost per connection will be reduced. We refer the readers to Rao and Hatamian (1995) for a discussion on the ATM physical layer issues.

TRAFFIC MANAGEMENT

In order for ATM networks to deliver guaranteed quality of service (QoS) on demand while maximizing the utilization of available network resources, effective traffic management mechanisms are needed. Almost every aspect of ATM network operation, from signaling requests and routing to network resource allocation and policing, contains some traffic management mechanisms (www.mfa-forum.org/ftp/pub/approved-specs/af-tm-0121.000.pdf).

A set of six service categories are specified. For each one, a set of parameters is given to describe both the traffic presented to the network, and the QoS which is required of the network.

Generic Functions

To meet the QoS objectives, the following functions form a framework for managing and controlling traffic and

congestion in ATM networks and may be used in appropriate combinations depending on the service category.

- *Network resource management*: is used in broadband networks to keep track of the way link resources are allocated to connections. The two primary resources that are tracked by network resource management are capacity (bandwidth) and connection identifiers. Network resource management keeps track of the capacity and controls the allocation of capacity to connections when requested as part of the connection setup process (Sexton and Reid 1997). In ATM, the service architecture allows logical separation of connections according to service characteristics. Although cell scheduling and resource provisioning are implementation and network specific, they can be utilized to provide appropriate isolation and access to resources. Virtual paths are a useful tool for resource management.

- *Traffic policing*: is monitoring network traffic for conformity with a traffic contract. An application that wishes to use the broadband network to transport traffic must first request a connection, which involves informing the network about the characteristics of the traffic and the quality of service (QoS) required by the application (Ferguson and Huston 1998). This information is stored in a traffic contract. If the connection request is accepted, the application is permitted to use the network to transport traffic.

The main purpose of this function is to protect the network resources from malicious connections and to enforce the compliance of every connection to its negotiated traffic contract. The network also has the capability to discard non-conformant traffic in the network (using priority control). Traffic policing in ATM networks is known as usage parameter control (UPC) and network parameter control (NPC) (Saito 1993).

- *Traffic shaping*: provides a mechanism to control the volume of traffic being sent into a network (bandwidth throttling), and the rate at which the traffic is being sent (rate limiting). For this reason, traffic shaping schemes are commonly implemented at the network edges to control traffic entering the network. The objectives of this function are to achieve a better network efficiency while meeting the QoS objectives and/or to ensure connection traffic conformance at a subsequent interface. Simple traffic shaping schemes like leaky bucket and token bucket rely on shaping all traffic uniformly by rate.

- *Connection admission control (CAC)*: Admission control is the simple practice of discriminating which traffic is admitted into a network in the first place (Ferguson and Huston 1998). Admission control in ATM networks is known as connection admission control (CAC) (Saito 1993).

Connection admission control is defined as the set of actions taken by the network during the call set-up phase in order to determine whether a connection request can be accepted or should be rejected (or whether a request for re-allocation can be accommodated).

- *Feedback controls*: are defined as the set of actions taken by the network and by end-systems to regulate the traffic submitted on ATM connections according to the state

of network elements. This specification defines one network feedback control mechanism: the ABR flow control. The ABR flow control may be used to adaptively share the available bandwidth among participating users.

- *Usage parameter control (UPC)*: is defined as the set of actions taken by the network to monitor traffic and enforce the traffic contract at the user network. Network parameter control (NPC) is a similarly defined set of actions at the Network Node Interface. The main purpose of UPC and NPC is to protect network resources from malicious as well as unintentional misbehavior, which can affect the QoS of other already established connections, by detecting violations of negotiated parameters and taking appropriate actions. Such actions may include cell discard and cell tagging.
- *Cell loss priority control*: For some service categories the end system may generate traffic flows of cells with cell loss priority (CLP) marking. The network may follow models which treat this marking as transparent or as significant. If treated as significant, the network may selectively discard cells marked with a low priority to protect, as far as possible, the QoS objectives of cells with high priority.
- *Frame discard*: A congested network that needs to discard cells may discard at the frame level rather than at the cell level.

Quality of Service Attributes

While setting up a connection on ATM networks, users can negotiate with the network the following parameters related to the desired quality of service:

- *Peak-to-peak cell delay variation (peak-to-peak CDV)*: The delay experienced by a cell between network entry and exit points is called the cell transfer delay (CTD). It includes propagation delays, queueing delays at various intermediate switches, and service times at queueing points.
The peak-to-peak CDV is the difference between the $(1 - \alpha)$ quantile of the CTD and the fixed CTD that could be experienced by any delivered cell on a connection during the entire connection holding time. The term "peak-to-peak" refers to the difference between the best and worst case of CTD, where the best case is equal to the fixed delay, and the worst case is equal to a value likely to be exceeded with probability no greater than α .
- *Maximum cell transfer delay (maxCTD)*: Cell delay variation (CDV) is a measure of variance of CTD. High variation implies larger buffering for delay sensitive traffic such as voice and video.
The maximum cell transfer delay (maxCTD) specified for a connection is the $(1 - \alpha)$ quantile of CTD. The CLR at connection request time is used to place an upper bound on α .
- *Cell loss ratio (CLR)*: The percentage of cells that are lost in the network because of error or congestion and are not delivered to the destination, i.e.,

$$\text{CLR} = \frac{\text{\# Lost Cells}}{\text{\# Transmitted Cells}}$$

Recall that each ATM cell has a cell loss priority (CLP) bit in the header. During periods of congestion, the network will first discard cells with $\text{CLP} = 1$. Because the loss of cells with $\text{CLP} = 0$ is more harmful to the operation of the application, CLR can be specified separately for cells with $\text{CLP} = 1$ and for those with $\text{CLP} = 0$.

All these parameters are described in details in the "Traffic Management Specification" document (www.mfaforum.org/ftp/pub/approved-specs/af-tm-0121.000.pdf).

Traffic Contract

To provide a guaranteed QoS, a traffic contract is established during connection setup, which contains a connection traffic descriptor and a conformance definition. However, it is not necessary for every ATM virtual connection to have a specified QoS. The reason for this is that if only specified QoS connections are supported by ATM, then a large percentage of the network resources will be wasted. This can happen when one or more connections are not utilizing the full capacity of their QoS contracts. Unspecified QoS contracts can be supported by an ATM network on a "best-effort" basis. Such best-effort services are sufficient for supporting most of the existing data applications.

In general, a traffic contract specifies one of the following six service categories:

- *Constant bit rate (CBR)*: This service category is used for emulating circuit switching, where the bit rate is constant. Cell loss ratio is specified for cells with $\text{CLP} = 0$ and may or may not be specified for cells with $\text{CLP} = 1$.
- *Real-time variable bit rate (rt-VBR)*: The real-time VBR service category is intended for real-time applications, i.e., those requiring tightly constrained delay and delay variation, as would be appropriate for voice and video applications. rt-VBR connections are characterized in terms of a peak cell rate (PCR), sustainable cell rate (SCR), and maximum burst size (MBS). Sources are expected to transmit at a rate that varies with time. Equivalently the source can be described as "bursty." Cells that are delayed beyond the value specified by maxCTD are assumed to be of significantly reduced value to the application. Real-time VBR service may support statistical multiplexing of real-time sources.
- *Non-real-time variable bit rate (nrt-VBR)*: The non-real-time VBR service category is intended for non-real-time applications that have bursty traffic characteristics and which are characterized in terms of a PCR, SCR, and MBS. For those cells that are transferred within the traffic contract, the application expects a low cell loss ratio. Non-real-time VBR service may support statistical multiplexing of connections. No delay bounds are associated with this service category.
- *Available bit rate (ABR)*: This service category is designed for normal data traffic such as file transfer and email. Although the standard does not require the cell transfer delay and cell loss ratio to be guaranteed, it is desirable for switches to minimize the delay and loss as much as possible. Depending upon the congestion state of the network, the source is required to control its rate. The users are allowed to declare a minimum cell rate (MCR), which is guaranteed to the VC by the

Table 1: ATM Service Category Attributes

	ATM Layer Service Category					
Attribute	CBR	rt-VBR	nrt-VBR	UBR	ABR	GFR
Traffic Parameters						
PCR and CDVT	Specified					
SCR, MBS, CDVT	n/a	Specified		n/a		
MCR	n/a				Specified	n/a
MCR, MBS, MFS CDVT	n/a					Specified
QoS Parameters						
Peak-to-peak CDV	Specified		Unspecified			
MaxCTD	Specified		Unspecified			
CLR	Specified			Unspecified	Network Specific	
Feedback	Unspecified				Specified	Unspecified

network. Most VCs will ask for an MCR of zero. Those with higher MCR may be denied connection if sufficient bandwidth is not available.

- *Unspecified bit rate (UBR)*: This service category is designed for those data applications that want to use any left-over capacity and are not sensitive to cell loss or delay. Such connections are not rejected on the basis of bandwidth shortage (i.e., no connection admission control) and not policed for their usage behavior. During congestion, the cells are lost but the sources are not expected to reduce their cell rate. Instead, these applications may have their own higher-level cell loss recovery and retransmission mechanisms. Examples of applications that use this service are email and file transfer. Of course, these same applications can use the ABR service, if desired.
- *Guaranteed frame rate (GFR)*: The GFR service category is intended to support non-real-time applications. It is designed for applications that may require a minimum rate guarantee and can benefit from accessing additional bandwidth dynamically available in the network. It does not require adherence to a flow control protocol. The service guarantee is based on AAL5 PDUs (frames) and, under congestion conditions, the network attempts to discard complete PDUs instead of discarding cells without reference to frame boundaries. On the establishment of a GFR connection, the end-system specifies a PCR, and a minimum cell rate (MCR) that is defined along with a maximum burst size (MBS) and a maximum frame size (MFS). The user may always send cells at a rate up to PCR, but the network only commits to carry cells in complete frames at MCR. Traffic beyond MCR will be delivered within the limits of available resources. There are no delay bounds associated with this service category.

These service categories relate traffic characteristics and QoS requirements to network behavior. Functions such as routing, CAC, and resource allocation are, in general, structured differently for each service category. Service categories are distinguished as being either real-time or non-real-time. For real-time traffic, there are two

categories, CBR and rt-VBR, distinguished by whether the traffic descriptor contains only the peak cell rate (PCR) or both PCR and the sustainable cell rate (SCR) parameters. All service categories, except GFR, apply to both VCCs and VPCs. GFR is a frame-aware service that only applies to VCCs since frame delineation is not usually visible at the virtual path level.

ABR or UBR are usually specified in the traffic contract when the ATM network is providing a best-effort service. Thus, these two classes of traffic are sometimes referred to as best-effort traffic. The attributes for the above service categories are summarized in Table 1.

Congestion Control Techniques

Congestion control lies at the heart of the general problem of traffic management for ATM networks. In general, congestion arises when the incoming traffic to a specific link is more than the outgoing link capacity. The primary function of congestion control is to ensure good throughput and delay performance while maintaining a fair allocation of network resources to the users (Jain 1990). For unspecified QoS traffic such as ABR service, whose traffic patterns are often highly bursty and unpredictable, congestion control poses more challenges than for other services.

As described in Jain (1992), one way to classify congestion control schemes is based on the layer of ISO/OSI reference model at which the scheme operates. For example, there are data link, routing, and transport layer congestion control schemes. Typically, a combination of such schemes is used. The selection depends upon the severity and duration of congestion. Figure 7 shows how the duration of congestion affects the choice of the method.

One method to avoid network congestion is to accept a new ATM connection during connection setup phase only when sufficient network resources are available to provide the acceptable QoS. This is called connection admission control (CAC), which is needed for connections where the QoS must be guaranteed. The “busy” tone on

Figure 7: Congestion techniques for various congestion durations

telephone networks is an example of CAC. Mechanisms for CAC are currently not standardized and are at the discretion of the network operators.

In addition to CAC, Traffic Management Specification Version 4.1 also allows traffic shaping using a generic cell rate algorithm (GCRA) and binary explicit forward congestion indication (EFICI) feedback congestion control. These mechanisms are described next.

Generic Cell Rate Algorithm (GCRA)

The GCRA is also called the “leaky bucket” algorithm, which converts a bursty stream into a more regular pattern. This algorithm essentially works by putting all arriving cells into a bucket, which is drained at the sustained cell rate. If too many cells arrive at once, the bucket may overflow. The overflowing cells are called non-conforming and may or may not be admitted into the network. If admitted, the cell loss priority (CLP) bit of the non-conforming cells may be set so that they will be the first to be discarded in case of overload.

The leaky bucket algorithm is often used by the network to ensure that the input meets the pre-negotiated parameters such as the sustained and peak cell rates. Such “traffic shaping” algorithms are open loop in the sense that the parameters cannot be changed dynamically if congestion is detected after negotiation. In a closed-loop (feedback) scheme, however, sources are informed dynamically about the congestion state of the network and are asked to increase or decrease their input rate.

Feedback Congestion Control

As described earlier in Figure 3, four bits of the cell header at the user-network interface (UNI) are reserved for generic flow control (GFC). Originally, the plan was to use these bits to flow control the source. The discussions in ATM Forum eventually led to the development of end-to-end congestion control scheme instead of GFC.

An effective congestion control scheme must satisfy several key criteria. In addition to being able to maximally utilize available bandwidth, a good scheme must also provide fairness of network resources to users. Moreover, it must be scalable to a large number of nodes and links with various capacities, robust against slight mistuning of parameters and loss of control cells, as well as low in switch complexity and buffer requirement.

The ATM Forum initially considered the use of the explicit forward congestion indication (EFICI) bit in the ATM cell headers to mark congestion in the switches (Hluchyj et al. 1993). This scheme was to be based on DECbit scheme (Ramakrishnan and Jain 1990). The

forum finally adopted an explicit rate-based indication scheme based on Charny et al. (1995).

The available bit rate (ABR) method of traffic management works as follows. The sources periodically send resource management (RM) cells, which indicate their current rate and the desired rate. The switches along the path adjust the desired rate down. The destination returns the RM cells to the sources. The sources then adjust their rate to that indicated in the RM cells. The algorithm for deciding the rate allocated by a switch is not specified and is left for the vendors to design. For examples of such algorithms, see Jain et al. (1995), Kalyanaraman et al. (2000), and Roberts (1994).

The rate-based congestion control approach and its development at the ATM Forum is described in more detail in www.mfaforum.org/ftp/pub/approved-specs/af-tm-0121.000.pdf. Other reference sources include the review papers of Jain (1996) and Bonomi and Fendick (1995).

SWITCH ARCHITECTURE

Perhaps the most developed aspect of ATM is the switch architecture. Over the past decade, a vast amount of research efforts have been made on studying and designing ATM switches. The field has now become a mature research area and a number of tutorial articles have appeared in the literature. The design of ATM switch architectures is at the discretion of switch vendors. Basic principles of switch design and examines the influence of traffic patterns on the design methodologies are discussed in Chen and Liu (2003), Awdeh and Mouftah (1995), and Simcoe and Pei (1995).

ATM switches are high-speed packet switches specialized to process and forward ATM cells (packets). Because ATM is a connection-oriented protocol, ATM switches must establish a virtual connection from one of its input ports to an output port before forwarding incoming ATM cells along that virtual connection.

A generic ATM switch architecture with N input ports and N output ports is shown in Figure 8. The functions of an ATM switching system may be divided broadly into the three planes as in Chen and Liu (2003).

- *User plane:* The main function of an ATM switch is to relay user data cells from input ports to the appropriate output ports. The switch processes only the cell headers and the payload is carried transparently. As soon as the cell comes in through the input port, the virtual path identifier/virtual channel identifier (VPI/VCI) information is derived and used to route the cells to the appropriate output ports. This function can be divided into three functional blocks: the input module at the input port, the cell switch fabric (sometimes referred to as switch matrix) that performs the actual routing, and the output modules at the output ports.
- *Control plane:* This plane represents functions related to the establishment and control of the VP/VC connections. Unlike the user data cells, information in the control cells payload is not transparent to the network. The switch identifies signaling cells, and even generates some itself. The connection admission control (CAC) carries out the major signaling functions required. Signaling information may/may not pass through the cell

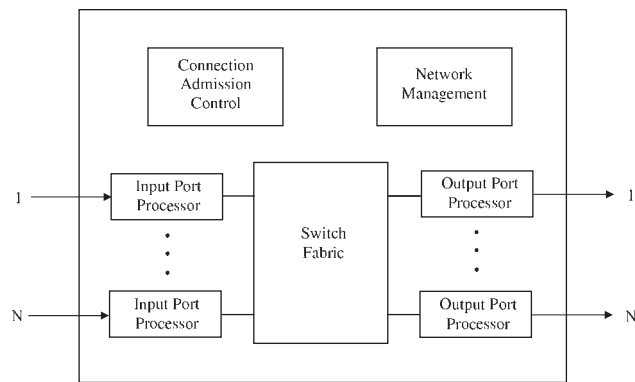

Figure 8: A generic ATM switch architecture

switch fabric, or may be exchanged through a signaling network such as SS7.

- *Management plane:* The management plane is concerned with monitoring the controlling the network to ensure its correct and efficient operation. These operations can be subdivided as fault management functions, performance management functions, configuration management functions, security management functions, accounting managements, and traffic management. These functions can be represented as being performed by the functional block switch management. The switch management is responsible for supporting the ATM layer operations and maintenance (OAM) procedures. OAM cells may be recognized and processed by the ATM switch. The switch must identify and process OAM cells, maybe resulting in generating OAM cells. As with signaling cells, OAM cells may/may not pass through cell switch fabric. Switch management also supports the interim local management interface (ILMI) of the UNI. The switch management contains, for each UNI, a UNI management entity (UME), which may use SNMP.

ATM cells containing user data are received at the input ports, and the input port processors prepare the cells for routing through the switch fabric. The fabric in the center of the switching system provides the interconnections between input port processors and output port processors. The output port processors prepare the outgoing user cells for transmission from the switch. User cell forwarding is characterized by parallelism and high-speed hardware processing. The ATM protocol was intentionally streamlined to allow incoming cells to be processed simultaneously in hardware and routed through the switch fabric in parallel. Thus, ATM switches have been able to realize high-end performance in terms of throughput and cell forwarding delay.

An ATM switch contains a set of input ports and output ports, through which it is interconnected to users, other switches, and other network elements. It might also have other interfaces to exchange control and management information with special purpose networks. Connection control, sometimes called the control plane, refers to the functions related to the establishment and termination of ATM virtual connections. Connection control functions generally encompass: exchange and processing of signaling information; participation in

routing protocols; and decisions on admission or rejection of new connection requests.

The cell switch fabric is primarily responsible for routing of data cells and possibly signaling and management cells as well. Other possible functions include: cell buffering, traffic concentration and multiplexing redundancy for fault tolerance, multicasting or broadcasting, cell scheduling based on delay priorities, congestion monitoring, and activation of explicit forward congestion indication (EFCI). More details about switch fabrics can be found in Chen and Liu (2003) and Awdeh and Mouftah (1995).

Network management is currently carried out by SNMP (simple network management protocol), the standard protocol for managing data networks. ATM switches typically support an SNMP agent and an ATM MIB (management information base).

Switch Interface

Input Modules

The input module first terminates the incoming signal (for example a SONET signal) and extracts the ATM cell stream. This involves signal conversion and recovery, processing SONET overhead, and cell delineation and rate decoupling. After that, for each ATM cell the following functions should be performed:

- Error checking the header using the header error control (HEC) field
- Validation and translation of VPI/VCI values
- Determination of the destination output port
- Passing signaling cells to CAC and OAM cells to switch management
- UPC/UNC for each VPC/VCC
- Addition of an internal tag containing internal routing and performance monitoring information for use only within the switch

Output Modules

Output modules prepare the ATM cell streams for physical transmission by:

- Removing and processing the internal tag
- Possible translation of VPI/VCI values
- HEC field generation
- Possible mixing of cells from CAC and switch management with outgoing cell streams
- Cell rate decoupling
- Mapping cells to SONET payloads and generation of SONET overhead
- Conversion of the digital bitstream to an optical signal

Connection Admission Control (CAC)

CAC establishes, modifies and terminates virtual path/channel connections. More specifically, it is responsible for:

- High-layer signaling protocols
- Signaling ATM adaptation layer (AAL) functions to interpret or generate signaling cells

- Interface with a signaling network
- Negotiation of traffic contracts with users requesting new VPCs/VCCs
- Renegotiation with users to change established VPCs/VCCs
- Allocation of switch resources for VPCs/VCCs, including route selection
- Admission/rejection decisions for requested VPCs/VCCs
- Generation of UPC/NPC parameters

If the CAC is centralized, a single processing unit would receive signaling cells from the input modules, interpret them, and perform admission decisions and resource allocation decisions for all the connections in the switch. CAC functions may be distributed to blocks of input modules where each CAC has a smaller number of input ports. This is much harder to implement, but solves the connection control processing bottleneck problem for large switch sizes, by dividing this job to be performed by parallel CACs. A lot of information must be communicated and coordinated among the various CACs (Chen and Liu 2003). Some of the distributed CAC functions can also be distributed among output modules which can handle encapsulation of high-layer control information into outgoing signaling cells.

Switch Management

Switch management physical layer OAM, ATM layer OAM, configuration management of switch components, security control for the switch database, usage measurements of the switch resources, traffic management, administration of a management information base, customer-network management, interface with operations systems and finally support of network management.

Switch management is difficult because management covers an extremely wide spectrum of activities. In addition, the level of management functions implemented in the switch can vary between minimal and complex.

Switch management must perform a few basic tasks. It must carry out specific management responsibilities, collect and administer management information, communicate with users and network managers, and supervise and coordinate all management activities. Management functions include fault management, performance management, configuration management, accounting management, security management, and traffic management. Carrying out these functions entails a lot of intraswitch communication between the switch management and other functional blocks.

A centralized switch management can be a performance bottleneck if it is overloaded by processing demands. Hence, switch management functions can be distributed among input modules, but a lot of coordination would be required. Each distributed input module switch management unit can monitor the incoming user data cell streams to perform accounting and performance measurement. Output module switch management units can also monitor outgoing cell streams (Chen and Liu 2003).

The Cell Switch Fabric

The cell switch fabric is primarily responsible for transferring cells between the other functional blocks (routing of data cells and possibly signaling and management cells as well). Other possible functions include:

- Cell buffering
- Traffic concentration and multiplexing
- Redundancy for fault tolerance multicasting or broadcasting
- Cell scheduling based on delay priorities
- Congestion monitoring and activation of explicit forward congestion indication (EFCI)

Concentration, Expansion, and Multiplexing

Traffic needs to be concentrated at the inputs of the switching fabric to better utilize the incoming link connected to the switch. The concentrator aggregates the lower variable bit rate traffic into higher bit rate for the switching matrix to perform the switch at standard interface speed. The concentration ratio is highly correlated with the traffic characteristics, so it needs to be dynamically configured. The concentrator can also aid in dynamic traffic distribution to multiple routing and buffering planes, and duplication of traffic for fault tolerance. At the outputs of the routing and buffering fabric, traffic can be expanded and redundant traffic can be combined.

Routing and Buffering

The routing and buffering functions are the two major functions performed by the cell switch fabric. The input module attaches a routing tag to each cell, and the switch fabric simply routes the arriving cells from its inputs to the appropriate outputs. Arriving cells may be aligned in time by means of single-cell buffers. Because cells may be addressed to the same output simultaneously, buffers are needed. Several routing and buffering switch designs have aided in setting the important switch design principles. All current approaches employ a high degree of parallelism, distributed control, and the routing function is performed at the hardware level.

Traditionally switching has been defined to encompass either space switching or time switching or combinations of both techniques. The classification adopted here is slightly different in the sense that it divides the design approaches under the following four broad categories: (1) shared memory, (2) shared medium, (3) fully interconnected, and (4) space division (Chen and Liu 2003).

Shared Memory Approach: Figure 9 illustrates the basic structure of a shared memory switch. Here incoming cells are converted from serial to parallel form, and written sequentially to a dual-port random access memory. A memory controller decides the order in which cells are read out of the memory, based on the cell headers with internal routing tags. Outgoing cells are demultiplexed to the outputs and converted from parallel to serial form.

This approach is an output queueing approach, where the output buffers all physically belong to a common buffer pool. The approach is attractive because it achieves 100 percent throughput under heavy load. The

Figure 9: Basic structure of a shared-memory switch

buffer sharing minimizes the amount of buffers needed to achieve a specified cell loss rate. This is because if a large burst of traffic is directed to one output port, the shared memory can absorb as much as possible of it.

The approach, however, suffers from a few drawbacks. The shared memory must operate N times faster than the port speed because cells must be read and written one at a time. As the access time of memory is physically limited, the approach is not very scalable. The product of the number of ports times port speed (NV) is limited. In addition, the centralized memory controller must process cell headers and routing tags at the same rate as the memory. This is difficult for multiple priority classes, complicated cell scheduling, multicasting, and broadcasting.

Shared Medium Approach: Cells may be routed through a shared medium, like a ring, bus or dual bus. Time-division multiplexed buses are a popular example of this approach, and Figure 10 illustrates their structure. Arriving cells are sequentially broadcast on the TDM bus in a round-robin manner. At each output, address filters pass the appropriate cells to the output buffers, based on their routing tag. The bus speed must be at least NV for cells to eliminate input queueing.

The outputs are modular, which makes address filters and output buffers easy to implement. Also the broadcast-and-select nature of the approach makes multicasting and broadcasting straightforward. As a result, many such switches have been implemented, such as IBM's Packetized Automated Routing Integrated System (PARIS) and plaNET, NEC's ATM Output Buffer Modular Switch (ATOM), and Fore Systems' ForeRunner ASX-100 to mention a few (Onvural 1994). The Synchronous Composite

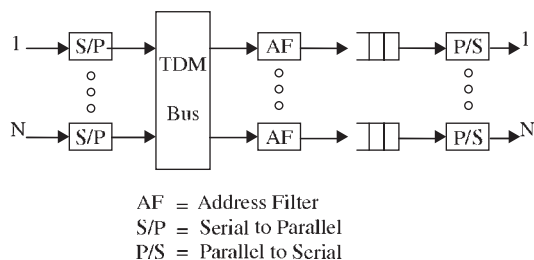

Figure 10: A shared bus switch (adapted from Chen and Liu 2003)

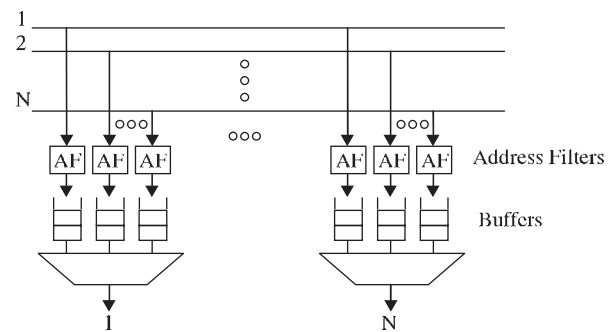

Figure 11: A fully interconnected switch (adapted from Chen and Liu 2003)

Packet Switching (SCPS), which uses multiple rings is also one of the most famous experiments of shared medium switches (Robertazzi 1993).

However, because the address filters and output buffers must operate at the shared medium speed, which is N times faster than the port speed, this places a physical limitation on the scalability of the approach. In addition, unlike the shared memory approach, output buffers are not shared, which requires more total amount of buffers for the same cell loss rate.

Fully Interconnected Approach: In this approach, independent paths exist between all N squared possible pairs of inputs and outputs. Hence arriving cells are broadcast on separate buses to all outputs and address filters pass the appropriate cells to the output queues. This architecture is illustrated in Figure 11.

This design has many advantages. As before, all queueing occurs at the outputs. In addition, multicasting and broadcasting are natural, like in the shared medium approach. Address filters and output buffers are simple to implement and only need to operate at the port speed. Because all of the hardware operates at the same speed, the approach is scalable to any size and speed. Fujitsu's bus matrix switch and GTE Government System's SPANet are examples of switches in which this design was adopted.

Unfortunately, the quadratic growth of buffers limits the number of output ports for practical reasons. However, the port speed is not limited except by the physical limitation on the speed of the address filters and output buffers.

The *Knockout* switch developed by AT&T was an early prototype where the amount of buffers was reduced at the cost of higher cell loss (Onvural 1994, Robertazzi 1993). Instead of N buffers at each output, it was proposed to use only a fixed number of buffers L for a total of $N \times L$ buffers. This technique was based on the observation that it is unlikely that more than L cells will arrive for any output at the same time. It was argued that selecting the L value of 8 was sufficient for achieving a cell loss rate of 1/1 million under uniform random traffic conditions for large values of N .

Space Division Approach: The *crossbar* switch is the simplest example of a matrix-like space division fabric that physically interconnects any of the N inputs to any of the N outputs. Multistage interconnection networks (MINs), which are more tree-like structures, were then

developed to reduce the N^2 crosspoints needed for circuit switching, multiprocessor interconnection and, more recently, packet switching.

One of the most common types of MINs is the banyan network. It is named for its resemblance to the roots of the Banyan tropical tree which crossover in complex patterns. The banyan network is constructed of an interconnection of stages of switching elements. A basic 2×2 switching element can route an incoming cell according to a control bit (output address). If the control bit is 0, the cell is routed to the upper port address, otherwise it is routed to the lower port address.

In general, to construct an $N \times N$ banyan network, the n^{th} stage uses the n^{th} bit of the output address to route the cell. For $N = 2$ to the power of n , the banyan will consist of $n = \log_2 N$ stages, each consisting of $N/2$ switching elements. A MIN is called self-routing when the output address completely specifies the route through the network (also called digit-controlled routing).

The banyan network technique is popular because switching is performed by simple switching elements, cells are routed in parallel, all elements operate at the same speed (so there is no additional restriction on the size N or speed V), and large switches can be easily constructed modularly and recursively and implemented in hardware.

It is clear that in a banyan network, there is exactly one path from any input to any output. Regular banyans use only one type of switching element, and SW-banyans are a subset of regular banyans, constructed recursively from $L \times M$ switching elements.

Delta networks are a subclass of SW-banyan networks, possessing the self-routing property. There are numerous types of delta networks, such as rectangular delta networks (where the switching elements have the same number of outputs as inputs), omega, flip, cube, shuffle-exchange (based on a perfect shuffle permutation), and baseline networks. A delta- b network of size $N \times N$ is constructed of $b \times b$ switching elements arranged in $\log_b N$ stages, each stage consisting of N/b switching elements (Robertazzi 1993).

Unfortunately, since banyan networks have less than N^2 crosspoints, routes of two cells addressed to two different outputs might conflict before the last stage. When this situation, called internal blocking, occurs, only one of the two cells contending for a link can be passed to the next stage, so overall throughput is reduced. A solution to this problem is to add a sort network (such as a Batcher bitonic sort network) to arrange the cells before the banyan network. This will be internally non-blocking for cells addressed to different outputs (Robertazzi 1993). However, if cells are addressed to the same output at the same time, the only solution to the problem is buffering. Buffers can be placed at the input of the Batcher network, but this can cause "head-of-line" blocking, where cells wait for a delayed cell at the head of the queue to go through, even if their own destination output ports are free. This situation can be remedied by First-In-Random-Out buffers, but these are quite complex to implement. Alternatively, buffers may be placed internally within the banyan switching elements. Thus if two cells simultaneously attempt to go to the same output link, one of them is buffered within the switching element. This internal buffering can also be used to implement a backpressure

control mechanism, where queues in one stage of the banyan will hold up cells in the preceding stage by a feedback signal. The backpressure may eventually reach the first stage, and create queues at the banyan network inputs (Chen and Liu 2003). It is important to observe that internal buffering can cause head-of-line blocking at each switching element, and hence it does not achieve full throughput. Awdeh and Mouftah (1994) have designed a delta-based ATM switch with backpressure mechanism capable of achieving a high throughput, while significantly reducing the overall required memory size.

A third alternative is to use a recirculating buffer external to the switch fabric. This technique has been adopted in Bellcore's Sunshine and AT&T's Starlite wideband digital switch (Robertazzi 1993). Here output conflicts are detected after the Batcher sorter, and a trap network selects a cell to go through, and recirculates the others back to the inputs of the Batcher network. Unfortunately, this approach requires complicated priority control to maintain the sequential order of cells and increases the size of the Batcher network to accommodate the recirculating cells (Chen and Liu 2003).

As discussed before, output buffering is the most preferable approach. However, banyan networks cannot directly implement it since at most one cell per cell time is delivered to every output. Possible ways to work around this problem include:

- Increasing the speed of internal links
- Routing groups of links together
- Using multiple banyan planes in parallel
- Using multiple banyan planes in tandem or adding extra switching stages

Apart from banyan networks, many types of MINs with multiple paths between inputs and outputs exist. Classical examples include the non-blocking Benes and Clos networks, the cascaded banyan networks, and the randomized route banyan network with load distribution (which eliminates internal buffering). Combining a number of banyan planes in parallel can also be used to form multipath MINs. The multipath MINs achieve more uniform traffic distribution to minimize internal conflicts, and exhibit fault tolerance. However if cells can take independent paths with varying delays, a mechanism is needed to preserve the sequential ordering of cells of the same virtual connection at the output. Since this might involve considerable processing, it is better to select the path during connection setup and fix it during the connection. Special attention must be paid during path selection to prevent unnecessary blocking of subsequent calls.

Switch Design Principles

Internal Blocking

A fabric is said to be internally blocking if a set of N cells addressed to N different outputs can cause conflicts within the fabric. Internal blocking can reduce the maximum possible throughput. Banyan networks are blocking, whereas TDM buses where the bus operates at least N times faster than the port speed are internally nonblocking. By the same concept, shared memory

switches which can read and write at the rate of NV cells per second are internally non-blocking, since if N cells arrive for N different outputs, no conflicts will occur. Hence, to prevent internal blocking, shared resources must operate at some factor greater than the port speed. Applying this to banyan networks, the internal links need to run square root of N times faster than the highest speed incoming link (Onvural 1994). This factor limits the scalability and throughput of the switch. Coppo et al. (1993) have developed a mathematical model for analyzing the optimal blocking probability versus complexity tradeoff.

Buffering Approaches

Buffering is necessary in all design approaches. For instance, in a banyan network, if two cells addressed to the same output successfully reach the last switching stage at the same time, output contention occurs and must be resolved by employing buffering. The location and size of buffers are important issues that must be decided (Onvural 1994).

There are four basic approaches to the placement of buffers. These basic approaches are illustrated in Figure 12. The literature abounds with comparative studies of these, augmented with numerous queueing analysis and simulation results. Uniform random traffic, as well as bursty traffic have been examined. Although each approach has its own merits and drawbacks, output queueing is the preferred technique so far.

Input Queueing: Buffers at the input of an internally nonblocking space division fabric (such as Batcher banyan network) illustrate this type of buffering. This approach suffers from head-of-the-line blocking. When two cells arrive at the same time and are destined to the same output, one of them must wait in the input buffers, preventing the cells behind it from being admitted. Thus capacity is wasted.

Several methods have been proposed to tackle the head-of-the-line blocking problem, but they all exhibit complex design. Increasing the internal speed of the space division

fabric by a factor of four, or changing the first-in-first-out (FIFO) discipline are two examples of such methods.

Output Queueing: This type of buffering can be evident by examining the buffers at the output ports of a shared bus fabric. This approach is optimal in terms of throughput and delays, but it needs some means of delivering multiple cells per cell time to any output. Hence, either the output buffers must operate at some factor times the port speed, or there should be multiple buffers at each output. In both cases, the throughput and scalability are limited, either by the speedup factor or by the number of buffers.

Internal Queueing: Buffers can be placed within the switching elements in a space division fabric. For instance, in a banyan network, each switching element contains buffers at its inputs to store cells in the event of conflict. Again, head-of-the-line blocking might occur within the switching elements, and this significantly reduces throughput, especially in the case of small buffers or larger networks. Internal buffers also introduce random delays within the switch fabric, causing undesirable cell delay variation.

Recirculating Buffers: This technique allows cells to re-enter the internally nonblocking space division network. This is needed when more than one cell is addressed to the same output simultaneously, so the extra cells need to be routed to the inputs of the network through the recirculating buffers. Although this approach has the potential for achieving the optimal throughput and delay performance of output queueing, its implementation suffers from two major complexities. First, the switching network must be large enough to accommodate the recirculating cells. Second, a control mechanism is essential to sequentially order the cells.

Buffer Sharing

The number and size of buffers has a significant impact on switch design. In shared memory switches, the central buffer can take full advantage of statistical sharing, thus absorbing large traffic bursts to any output by giving it as much as is available of the shared buffer space. Hence, it requires the least total amount of buffering. For a random and uniform traffic and large values of N , a buffer space of only $12 N$ cells is required to achieve a cell loss rate of $1/10$ to the power of 9, under a load of 0.9.

For a TDM bus fabric with N output buffers, and under the same traffic assumptions as before, the required buffer space is about $90 N$ cells. Also a large traffic burst to one output cannot be absorbed by the other output buffers, although each output buffer can statistically multiplex the traffic from the N inputs. Thus, buffering assumes that it is improbable that many input cells will be directed simultaneously to the same output.

Neither statistical multiplexing between outputs or at any output can be employed with fully interconnected fabrics with N squared output buffers. Buffer space grows exponentially in this case.

NEW DEVELOPMENTS

ATM could not fulfill the promise of providing a single integrated technology for LANs, public networks, and user

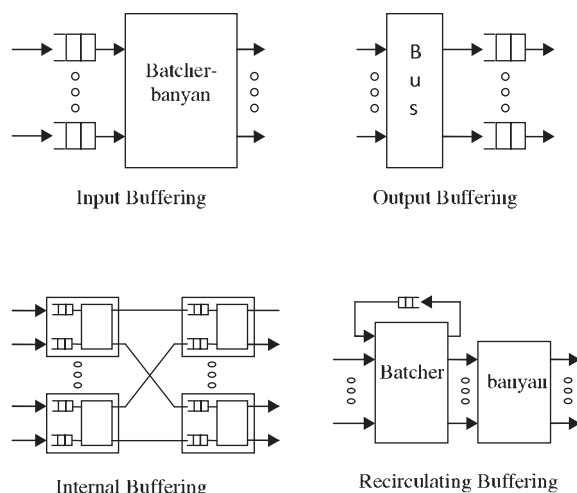

Figure 12: The various buffering approaches (combined from Chen and Liu 2003 and Onvural 1994)

services. IP was shown to provide such integration in a more flexible, more scalable, and less complex way than ATM. However, as it happens usually with technologies, the best ideas are borrowed by other solutions. In the case of ATM, various important concepts are inherited by other technologies, such as MPLS. Whereas other technologies, such as DSL, FTTP, and UMTS use ATM and AAL layers.

Multiprotocol Label Switching — (MPLS)

Multiprotocol label switching (MPLS) is a data-carrying mechanism which emulates some properties of a circuit-switched network over a packet-switched network (www.riverstonenet.com/support/mpls/intro_to_mpls.htm, www.ietf.org/html/charters/mpls charter.html, and Rosen et al. 2001). MPLS has emerged as an elegant solution to meet the bandwidth-management and service requirements for next-generation Internet protocol (IP)-based backbone networks. MPLS addresses issues related to scalability and routing (based on QoS and service quality metrics) and can exist over existing asynchronous transfer mode (ATM) and frame-relay networks. MPLS is standardized by IETF in RFC 3031 (Rosen et al. 2001). For ATM-MPLS network interworking see www.mfaforum.org/ftp/pub/approved-specs/af-aic-0178.001.pdf.

Although the underlying protocols and technologies are different, both MPLS and ATM provide a connection-oriented service for transporting data across computer networks. In both technologies connections are signaled between endpoints, connection state is maintained at each node in the path and encapsulation techniques are used to carry data across the connection. Excluding differences in the signaling protocols (RSVP/LDP for MPLS and PNNI for ATM) there still remain significant differences in the behavior of the technologies.

The most significant difference is in the transport and encapsulation methods. MPLS is able to work with variable length packets whereas ATM transports fixed-length (53 byte) cells. Packets must be segmented, transported and re-assembled over an ATM network using an adaption layer, which adds significant complexity and overhead to the data stream. MPLS, on the other hand, simply adds a label to the head of each packet and transmits it on the network.

Differences exist, as well, in the nature of the connections. An MPLS connection (LSP) is unidirectional, allowing data to flow in only one direction between two endpoints. Establishing two-way communications between endpoints requires a pair of LSPs to be established. Because two LSPs are required for connectivity, data flowing in the forward direction may use a path different from data flowing in the reverse direction. ATM point-to-point connections (Virtual Circuits), on the other hand, are bi-directional, allowing data to flow in both directions over the same path (bi-directional are only SVC ATM connections; PVC ATM connections are uni-directional).

Both ATM and MPLS support tunneling of connections inside connections. MPLS uses label stacking to accomplish this while ATM uses virtual paths. MPLS can stack multiple labels to form tunnels within tunnels. The ATM virtual path indicator (VPI) and virtual circuit

indicator (VCI) are both carried together in the cell header, limiting ATM to a single level of tunneling.

The biggest single advantage that MPLS has over ATM is that it was designed from the start to be complimentary to IP. Modern routers are able to support both MPLS and IP natively across a common interface allowing network operators great flexibility in network design and operation. ATM's incompatibilities with IP require complex adaptation making it largely unsuitable in today's predominantly IP networks.

Technologies Exploiting ATM and AAL Layers

DSL

DSL or xDSL is a family of technologies that provide digital data transmission over the wires of a local telephone network. DSL originally stood for digital subscriber loop, although in recent years, many have adopted digital subscriber line as a more marketing-friendly term for the most popular version of DSL, ADSL over UNE.

Typically, the download speed of DSL ranges from 128 kilobits per second (kbps) to 24,000 kbps depending on DSL technology and service level implemented. Upload speed is lower than download speed for asymmetric digital subscriber line (ADSL) and equal to download speed for symmetric digital subscriber line (SDSL).

Many DSL technologies implement an ATM layer over the low-level bitstream layer to enable the adaptation of a number of different technologies over the same link.

DSL implementations may create bridged or routed networks. In a bridged configuration, the group of subscriber computers effectively connect into a single subnet. The earliest implementations used DHCP to provide network details such as the IP address to the subscriber equipment, with authentication via MAC address or an assigned host name. Later implementations often use PPP over Ethernet (PPPoE) or ATM (PPPoA), while authenticating with a userid and password and using PPP mechanisms to provide network details (Mamakos et al. 1999, Kaycee et al. 1998).

PPPoA, Point-to-Point Protocol (PPP) over ATM, is a network protocol for encapsulating PPP frames in ATM AAL5. It is used mainly with cable modem, DSL, and ADSL services.

PPPoA offers standard PPP features such as authentication, encryption, and compression. If it is used as the connection encapsulation method on an ATM based network it can reduce overhead slightly (around 0.58 percent) in comparison to PPPoE (Mamakos et al. 1999). It also avoids the issues that PPPoE suffers from, related to having a MTU lower than that of standard ethernet transmission protocols. It also supports (as does PPPoE) the encapsulation types: VC-MUX and LLC based. PPPoA is specified in RFC 2364 (Kaycee et al. 1998).

Fiber to the Premises

Fiber to the premises (FTTP) or fiber to the home (FTTH) is a broadband telecommunications system based on fiber-optic cables and associated optical electronics for

delivery of multiple advanced services such as the triple play of telephone, broadband Internet, and television all the way to the home or business.

Two competing FTTP technologies are active FTTP, also called active Ethernet, and passive optical network (PON) architectures.

Active FTTP networks utilize powered (i.e., “active”) electronic equipment in neighborhoods, usually one equipment cabinet for every 400 to 500 subscribers. This neighborhood equipment performs layer 2/layer 3 switching and routing, offloading full layer 3 routing to the carrier’s central office. The IEEE 802.3ah standard enables service providers to deliver up to 100 Mbps full-duplex over one single-mode optical fiber to the premises depending on the provider.

Passive optical network (PON) FTTP networks on the other hand avoid the placement of electronics in the field. PON networks use passive splitters to distribute fiber to individual homes. One fiber is optically split into 16, 32, or 64 fibers, depending on the manufacturer, which are then distributed to residential or business subscribers. In PON architectures, the switching and routing is done at the carrier’s central office.

The International Telecommunications Union (ITU) has standardized on two generations of PON. The older ITU-T G.983 standard is based on ATM, and has therefore been referred to as APON (ATM PON) [7]. Further improvements to the original APON standard—as well as the gradual falling out of favor of ATM as a protocol—led to the full, final version of ITU-T G.983 being referred to more often as Broadband PON, or BPON. A typical APON/BPON provides 622 megabits per second (Mbps) of downstream bandwidth and 155 Mbps of upstream traffic, although the standard accommodates higher rates.

UMTS Core Network

ATM is also the data transmission method used within the universal mobile telecommunications system (UMTS) core network [24]. ATM adaptation layer type 2 (AAL2) handles circuit-switched connections. Packet connection protocol AAL5 is used for data delivery.

CONCLUSION

In this brief chapter, we have discussed several key aspects of ATM. ATM is a cell-oriented switching and multiplexing technology that uses fixed-length cells to carry various types of traffic, such as data, voice, video, multimedia, and so on through multiple classes of services.

ATM is a connection-oriented technology, in which a connection is established between the two endpoints before the actual data exchange begins.

The ATM protocol reference model is divided into three layers: the ATM adaptation layer (AAL), the ATM layer, and the physical layer, and three planes: user/control plane, layer management, and plane management. Four types of AALs were proposed, each supporting a different type of traffic or service that could be used on ATM networks.

ATM was designed to deliver guaranteed quality of service on demand while maximizing the utilization of

available network resources. Therefore, effective traffic management mechanisms were specified.

ATM has been a partial success as a technology, with widespread deployment, but generally only used as a transport for IP traffic; its goal of providing a single integrated technology for LANs, public networks, and user services has largely failed. This role of integrator in today’s networks is played by IP. However, various important ATM concepts are inherited by other technologies, such as MPLS, DSL, and FTTH. It is expected that the best ideas and lessons of ATM will be used in designing the next Internet.

GLOSSARY

- AAL:** ATM adaptation layer.
- ABR:** Available bit rate.
- ANSI:** American national standards institute.
- ATM:** Asynchronous transfer mode.
- ATMF:** ATM Forum.
- B-ISDN:** Broadband-integrated services digital network.
- BT:** Burst tolerance.
- CAC:** Connection admission control.
- CBR:** Constant bit rate.
- CDV:** Cell delay variation.
- CDVT:** Cell delay variation tolerance.
- CLP:** Cell loss priority.
- CLR:** Cell loss ratio.
- CRC:** Cyclic redundancy check.
- CS:** Convergence sublayer.

- MIB:** Management information base.
- MPLS:** Multi-protocol label switching.
- NDIS:** Network driver interface specification.
- NNI:** Network-to-node interface, or network to network interface.
- nrt-VBR:** non real-time VBR.
- PCR:** Peak cell rate.
- PDH:** Plesiochronous digital hierarchy.
- PNNI:** Private network-to-network interface.
- PTI:** Payload type identifier.
- PVC:** Permanent virtual circuit.
- QoS:** Quality of service.
- rt-VBR:** Real-time VBR.
- RSVP:** Resource reservation protocol.
- SAR:** Segmentation and reassembly.

SCR: Sustainable cell rate.
SDH: Synchronous digital hierarchy.
SONET: Synchronous optical network.
SSCOP: Service specific connection oriented protocol.
SVC: Switched virtual circuit.
VBR: Variable bit rate.
VC: Virtual channel.
VCC: Virtual channel connection.
VCI: Virtual channel identifier.
VPC: Virtual path connection.
VPI: Virtual path identifier.
UBR: Unspecified bit rate.
UNE: Unbundled network elements.
UMTS: Universal mobile telecommunication system.
UNI: User-to-network interface.

INTRODUCTION

Futuristic transmission systems will be based on fiber optic technology. Fiber optic network supports high-speed and low-delay data transfer required to meet the increasing demand for high bit-rate applications. A broadband service requires an information transfer rate exceeding the capacity of primary rate interface. Fiber optic network meets the bill of requirements for broadband service.

Narrow band-integrated services digital network (N-ISDN) (Kleinrock 1991) was the phoenix of the late 1990s. N-ISDN is a network providing end-to-end digital connectivity to support wide range of services. The basis of N-ISDN is a set of standards developed by CCITT. These standards were first issued in 1984. The N-ISDN standard is composed of two 64kbps B channel and a 16kbps signalling D channel. Each B channel can carry a separate telephone call and usually has its own telephone number called a directory number (DN). The B channels carry customer voice or data signals. The D channel carries signals between the ISDN equipment and the phone company's central office. The two bearer and one data channel are collectively called the basic rate interface (BRI).

The primary rate interface (PRI) is designed for businesses with larger data needs. The PRI offers 23 B channels for user information with one D channel operating at 64 kbps for user network signaling. It provides point-to-point connectivity between the network and a device requiring a significant amount of bandwidth. PRI is typically used as a trunk connection between the network and the PBX. PRI is capable of operating at 1.544 Mbps and 2.048 Mbps.

The N-ISDN physical layer is specified by the ITU I-series and G-series documents. The N-ISDN data link layer is specified by the ITU Q-series documents Q.920 through Q.923. Signaling on the D channel is defined in the Q.921 specification. N-ISDN builds upon the time division multiplexing (TDM) hierarchy. CCITT recommendation Q.931, defines a set of message types containing a number

of information elements used to establish and release N-ISDN bearer connections.

N-ISDN was designed to switch fixed-rate channels. Switching channels at different rates requires different switching fabrics, each of which is designed to switch at a specific rate. Switching applications are concerned with point-to-point applications. N-ISDN was not designed to support switching and transmission rates at speeds necessary for services like high-speed data transport for business applications and distribution of high definition television (HDTV) signals. N-ISDN is not a panacea for all computer-to-computer communications. (Handel 1989; Kleinrock 1991).

CCITT defines broadband service as a service requiring transmission channels capable of supporting rates greater than 1.5 Mbps or primary rate in N-ISDN or T1 or DS1 in digital terminology (Handel 1989). Broadband ISDN is a network architecture that uses newer switching and transmission technique suitable for high-speed operation. The compatibility of a broadband packet network with the existing circuit switched network and with public switched network needs critical attention. The major advantage of the packet approach to B-ISDN is the high degree of service integration.

The primary objective of this chapter is to provide information on the evolution of B-ISDN, related protocols, and interface structures.

EVOLUTION OF BISDN

Recognizing the service limits of N-ISDN, BISDN was designed to extend the important concepts of ISDN to provide a universal, long-term transport capability for all services. The drivers of this technology are the advances in the field of fiber optics, desire of extending fiber networks into subscriber loop area, distributed processing requirements, and interest in HDTV.

The subscriber loops are divided into feeder loops and distribution loops. In the feeder loop high-speed transmission systems are used to link remote terminals (RT) to the central office (CO). The RTs are provided with simple multiplexing functions or line concentration functions for more efficient utilization of the feeder bandwidth. The distribution loops have separate fibers for each direction of transmission.

The final step toward integration of the network and service was done by using ATM. Although it was envisaged that B-ISDN would follow the circuit switching philosophy of N-ISDN, the use of ATM transport has pushed it the next generation. The adoption of ATM switching and transfer mechanism as the backbone provided B-ISDN with the capability to meet technology and market uncertainties with the flexibility unavailable in N-ISDN. For fiber in the loop (FITL) applications the emergence of ATM means that a single transmission fabric can support all current types of traffic including supervisory functions.

The Plenary assembly of CCITT (Consultative Committee for International Telegraph and Telephone) adopted the I series recommendations dealing with N-ISDN. The recommendations were proposed to satisfy the needs of services employing bit rates greater than 2Mbps. Some of the services visualized include broadband video telephony, video surveillance, high-speed unrestricted digital information transmission, high-speed file transfer, video document retrieval service, and so on. To provide broadband services, new attribute values supplement CCITT recommendation I.130.

Broadband ISDN Standards

The earlier section provided an overview of the evolution of B-ISDN. The need for high-speed data transfer were identified. This section outlines the basic standards of B-ISDN.

Broadband ISDN was designed to be a long-term solution for the variety of services identified. The need to standardize the proposed protocols both nationally and internationally was understood. Efforts from various forums like CCITT, ANSI, and so on to standardize the relevant aspects of B-ISDN were underway between 1990 and 1992 (Murano et al. 1990). The standards were developed to enable a service requiring both large and small bandwidths to operate in a cost effective manner. The standards define the protocols required to interface other network services (such as switched multimegabit data services).

Taking cue from earlier works, which defined networks as a set of layers, each offering a class of transparent service to the layer above, B-ISDN standardization opted for layered architecture. Each layer established a virtual communication (peer-to-peer) with an associated layer. The set of layers and the associated set of protocols define the architecture of B-ISDN.

The ITU-T recommendation I.320 provides a description for the protocol reference model. I.320 provides the concept of plane separation for the user, control, and management functions. ITU-T I.321, which is built on I.320, exploits the proposed layered approach. I.321 B-ISDN protocol model defines the physical and ATM layers that are the foundation for user, control, and management planes.

B-ISDN Architecture

The B-ISDN standards expressed in the earlier section outline the B-ISDN architecture (Kawarasaki and Jabbari 1991). The B-ISDN architecture was designed to offer access to bandwidths up to 155Mbps. The B-ISDN's reference model is consistent with the N-ISDN's reference architecture. The reference architecture does not imply a physical implementation. It identifies the principal functional units which make up the network and the interfaces between them.

A functional reference architecture model for the broadband network is the conceptual division of functions that must be performed in transporting information through the network. The perception of B-ISDN's development profile required the proposal of distinct protocol sets serving control, user, service, and transport functions (Byrne et al. 1989). The protocols were divided into the service layer, consisting of user plane (U plane) and control plane (C plane), the adaptation layer, and the transport layer spanning the ATM and transmission functions.

The user plane provides user information to flow along the path with its associated control fields for flow control and error recovery. (See Figure 1.)

The control plane includes all connection control functions required for setting up a connection (connection setup) supervision and release. The control plane and its relationship to ATM is best described through network functions. The user network interface (UNI) is the demarcation point between the network and subscriber domains. The network termination (NT) provides a bridge between the subscribers' internal network and the UNI. Here the functions of NT encompasses cell multiplexing, concentration, buffering, and switching. Separation and conversion of data streams into subscriber-specific service protocols is the principal role of NT. NT is also provided with operation and maintenance (OAM) functions to permit network initiated UNI testing. Network network interface (NNI) defines the interface between ATM networks and ATM nodes.

The management plane provides layer and plane management functions.

The functional architecture consists of broadband distant terminals (BDT), access nodes, service nodes, and transport nodes interconnected by broadband facilities.

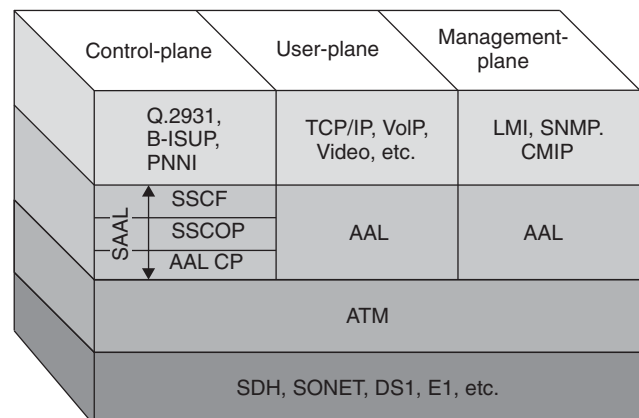

Figure 1: Protocol stack

BDT is positioned in the customer location and supports a variety of customer premises equipment (CPE) (Irvin 1990). Irvin has outlined the narrow band and broadband CPE directions. The functions of the BDT include media conversions, multiplexing and demultiplexing, signaling, and maintenance. BDT interfaces the customer terminal equipment with the fiber through the service or access nodes. It multiplexes information streams to the distribution fiber. It also demultiplexes the information streams, to various CPE (Irvin 1990). The distribution fiber uses SONET. The information carried over the broadband interface will vary both in terms of its service mix and the number of customers being served. The service nodes are interconnected through the transport network fibers. The transport nodes dynamically reroute traffic and cross connect fixed amount of bandwidth between service nodes. It provides a two-level transport hierarchy to interconnect service nodes. Light wave terminations, digital cross connects, add/drop multiplexing, and broadband packet cross connects are the functional components of the transport node.

B-ISDN Protocol Structure

Earlier the functional model of B-ISDN was discussed. This section provides an overview of the B-ISDN model of physical, ATM, and AAL layers. (Murano et al. 1990; Hac and Hasan 1989). (See Figure 2.)

The physical layer provides transmission of ATM cells over an electrical or optical physical transmission medium (Rider 1989). The physical layer is subdivided into two sublayers viz., the physical medium (PMD) sublayer and the transmission convergence (TC) sublayer.

PMD layer provides for the actual transmission of the bits in ATM cells. This layer interfaces with the electrical or optical transmission medium detecting the signals, transferring the bit stream and passing the bit stream to the transmission convergence (TC) sublayer.

The TC sublayer maps ATM cells from the TDM bit stream provided by the PMD sublayer. It provides five functions.

The TC sublayer takes care of generation and recovery of the transmission frame.

The transmission frame adaptation function adapts the received payload to the ATM cell structure. This layer transforms the flow of cells into a steady flow of bits and bytes for transmission over the physical medium such as DS1/E1, DS3/E3, or twisted-pair cabling within an office.

The cell delineation function enables the ATM receiver to recover cell boundaries. This is defined in ITU-T recommendation I.432.

The header error control (HEC) function is used prevent cells from reaching incorrect destinations when there are errors in the VCI or VPI fields.

The rate decoupling function inserts idle cells in the transmit direction to adapt the rate of ATM cells to the payload capacity of the transmission system.

The ATM layer performs multiplexing, switching, and control actions based on information in the ATM cell header and passes cells to AAL. The AAL layer is made up of segmentation and reassembly layer (SAR) and convergence sub-layer (CS). A common part (CP) component and a service specific component make up CS. The functions of AAL are described in ITU-T recommendation I.362.

Asynchronous Transfer Mode (ATM)

This section provides a brief overview of the concepts that make up ATM. ATM is a cell-based switching and multiplexing technology (Muthukumaran 2005). It is defined as an interface between the user and the network, and between networks. It takes the form of a network interface card, router, cross-connect, or an intelligent switch in the customer premises equipment. It is designed to switch any type of traffic over a common transmission medium. It offers service provider networks, the ability to simultaneously support video, voice, and data as an evolutionary successor to narrow band ISDN services.

ATM is a technology defined by protocols standardized by the ITU-T, ANSI, ETSI, and ATM forum. This is the technology of choice for the B-ISDN. This is considered to be the ground on which B-ISDN is built. ATM has the same basic characteristics of packet switching and delay of circuit switching.

Cell: ATM defines a mechanism to carry all traffic on a stream of fixed 53-byte packets. (See Figure 3.) The reasons

Figure 2: B-ISDN

Figure 3: Cell structure

for fixing 53 bytes are discussed extensively by Prasanna (Zoccolillo and Prasana, 1989). These packets are called cells. According to ITU-T, a cell is a block of fixed length. It is identified at the ATM layer of B-ISDN. All packets in the network are of fixed length and hence are called cells.

The cell forms the basic element of the ATM layer. The ATM cell is made up of two parts: the header and the information (data). The data part is called the ATM payload. The cell header part is made up of 5-octets and the information part is made up of 48-octets giving a total of 53-octets. The job of the ATM header is to identify the characteristics of the virtual channel on a multiplex link. The information contained in the ATM header is designed to invoke functions that are internal and specific to the individual node. The header is made to carry only those attributes that define cell-by-cell variances. Attributes like traffic routing, data integrity and operations are required for connection maintenance.

The header is independent of service and transmission systems. The onus of service related attributes is given to the signalling system. Cell sequence identification in the ATM header is used to satisfy the requirements of cell ordering and cell loss.

Some of the functions contained in the cell header include:

- Generic flow control (GFC)
- A virtual path identifier (VPI)
- A virtual circuit identifier (VCI)
- A header error control (HEC)
- A payload type (PT)

The GFC exist in the UNI interface and is not present in the NNI interface. GFC is implemented to alleviate short term overload conditions that may occur. This implementation allows a terminal to achieve assured capacity or bandwidth allocated by the network to both VBR and CBR calls.

The B-ISDN interface between the customer and the network consists of ATM cells. The cells are multiplexed from several logical connections onto one physical interface.

ATM Virtual Channels and Paths

The ATM layer has two hierarchical levels, viz. a virtual channel and a virtual path level. A virtual channel is a bi-directional logical connection between the ends of a communication connection. A virtual channel is identified by

Figure 4: Transmission path

the information carried in the header and by the attributes provided by the signaling protocol. There is a connection identifier in every cell header which explicitly associates a cell with a given virtual channel on a physical link. The connection identifier consists of two subfields, the virtual channel identifier (VCI) and the virtual path identifier (VPI). Coding for these levels is based on the use of VCI and VPI. The VCI is used to identify the logical channel connections and provides the basis for routing the cells. ATM standard specifies virtual channel connections (VCC) and virtual path connections (VPC). Together they are used in multiplexing, demultiplexing, and switching a cell through the network. When a virtual channel spans multiple links each link can potentially have a different VCI for the VC. The header contains at least one VCI.

The virtual path concept originated with concerns over the cost of controlling B-ISDN networks. A virtual path is bidirectional logical grouping of VCs that have the same destination. (See Figure 4.) Virtual paths are semi-permanent connections and the routing tables for the VP switch are preset by the network management functions. The plan was to group connections sharing common paths through the network into identifiable units. Network management actions including call set up, routing, failure management, bandwidth allocation, and so on, would then be applied to the smaller number of groups of paths instead of a larger number of individual connections (VCI).

The VPI is 8-bits at the user network interface and 12-bits at the network interface. The VP switch translates the VPI and VCI values. The VPI and the VCI together form the routing field, which associates each cell with a particular channel or circuit.

VP cross-connect is a network element which connects VP links. It translates VPI (not VCI) values and is directed by management plane functions and not by control plane functions. VC switch is a network element that connects VC links. It terminates VP connections, translates VCI values and is directed by control plane functions.

Adaptation Layers

Connection-oriented and connectionless, packet transfer services require an adaptation layer to provide segmentation and reassembly of the data packets into ATM cells. The efficient packing and reconstruction of services at ATM transport boundaries are essential to the successful utilization of ATM. ATM was not designed to be independent of the various communication services that may be using the network. ATM adaptation layer (AAL) was designed to achieve the complementary functions that make

the data stream exchanged from end-to-end compatible with the requirements. The adaptation layer protocols remain transparent to ATM and lower layer protocols. The adaptation layer allows higher layer information of either the user plane or the control plane to be mapped to the ATM layer. The adaptation protocols provide alignment of service specific data structures with ATM cell payloads. CCITT recommendations I.362 and I.363 provide the definitions and specifications of AALs.

The AAL is organized in two logical sublayers, viz. convergence sublayer and segmentation and reassembly sublayer. The convergence sublayer generally provides the functions required to provide specific applications using AAL. The segmentation and reassembly sublayer is responsible for packaging the data received into cells for further transmission and unpacking the information at the other end. AAL layer provides the following services.

AAL-1 supports connection-oriented services that require constant bit rates and have specific timing and delay requirements. This is designed to carry voice and to emulate the characteristics of a TDM connection. This layer accepts a stream of incoming bytes.

AAL-2 provides for efficient transmission of variable length packets in delay sensitive applications and supports the transfer of time-sensitive constants as well as variable bit rate traffic. It consists of variable size packets encapsulated within the ATM payload. This was previously known as composite ATM or AAL-CU.

The AAL-3 and AAL4 specifications were originally almost identical in terms of PDU structure and functionality and hence were merged into AAL3/4. This layer provides connection oriented and connectionless variable bit rate services.

The AAL-5 layer supports connection-oriented variable bit rate data services. Message mode service and streaming mode service are two defined service modes. Message mode is used for framed data. Streaming mode is used for data separated in time.

Why were so many AAL layers designed when everything ends up packed into the 48-byte payload of ATM cells? We can answer this question based on the differences between key attributes supported by each AAL.

ATM implementations are based on switching and multiplexing technologies that induce very little delay in terms of the cell transmission time. They require very little variation in inter-cell delay to avoid "jitter" in voice applications. These systems utilize space division multiplexing also known as asynchronous time division multiplexing. The key characteristics of ATM are rate adaptation to support multimedia traffic and statistical multiplexing.

BROADBAND TRANSPORT

Traffic management is a set of network actions that monitor and control the flow of traffic (Amin-Salehi and Spears 1989). It is the act of managing network traffic, providing service guarantees to user connections, and ensuring optimal utilization of resources.

Basic traffic control functions of the ATM-based B-ISDN transport network are connection admission control (CAC) and usage parameter control (UPC). The main

function of CAC is to accept or reject a connection request based on whether the available bandwidth in the network can satisfy the requirement of this connection. The bandwidth requirement of a connection can be expressed in terms of traffic descriptors such as peak rate, average rate, and burst length (Kawarasaki and Jabbari 1991). These traffic descriptors will then be monitored by the UPC function, and when the cells violating the negotiated parameter value are introduced to a network, these cells will be discarded or tagged by the network to ensure the negotiated performance of other existing connections.

Traffic characteristics of B-ISDN includes traffic parameters like call duration, bandwidth burstiness, and impairment. The traffic may consist of separate traffic streams that must be logically and physically bundled for integrated customer access but may be switched and processed separately in the network. Broadband network services require transmission medium for customer access and interoffice facilities. Optical fibers were preferred to be the optimal medium of transmission for broadband communications. Optical fibers provided low transmission loss, immunity from electromagnetic interference, and large information carrying capacity. Subscriber channels transported over optical fibers are multiplexed using SONET multiplexers.

SONET

B-ISDN transport architecture is based on the SONET protocol. It is used as physical interface for broadband services. Synchronous Optical Network (SONET) (Ballart and Ching 1989; Lee and Aprille 1991) is a North American standard for networking developed in the mid-1980's primarily by Bellcore and standardized by ANSI. It defines a digital hierarchy of synchronous signals including their formats and mappings of asynchronous signals (e.g., DS-1, DS-3) into these formats and defines the electrical and optical characteristics of the interface. This is byte interleaved synchronous digital hierarchy that consists of a family of standard electrical synchronous transport signals (STS).

SONET provides a set of standard transmission interfaces, interfaces for CPE, switches, interfaces, and interoffice transport systems. SONET frames allow for both voice channels and broadband services, and they carry framing overhead that is not embedded in the cell structure. Transport overhead is distributed throughout the frame. Each frame consists of 9 bytes of section overhead, 18 bytes of line overhead, 9 bytes of path overhead, and 774 bytes of payload transmitted in a pattern of 3 bytes of section/line overhead followed by 87 bytes of payload plus path overhead. An STS-N signal contains N copies of the section, line, and path overheads. If an STS-N signal is sent between two multiplexers with no intervening demultiplexing, it is permitted to send only one copy of the path overhead. SONET bit rates are integer multiples of 51.730 megabits per second. The base bit stream is made up of 125 microsecond frames of 810 bytes, where the bit rate is the integer part of the calculated bit rate. The B-ISDN user network interfaces will use two bit rates: 150 megabits per second and 600 megabits per second.

The basic SONET entity is the synchronous transport signal-1 (STS-1). It operates at 51.84 Mbps, of which 49.5 Mbpsec is usable payload and the rest is overhead. The

STS-1 frame structure is byte-oriented has 9 rows and 90 columns, four of which are used for overhead purposes. The frame rate is 8000/second (125 s/frame). Normally all SONET signals are bidirectional and run at the same rates in each direction. An STS- n signal ($n > 1$) is formed by byte-interleaving n STS-1's together.

Higher layer communication protocols will be based on the strengths of SONET. The bandwidth of ATM channel is determined by the rate at which cells are placed into the transmission stream. Explicit channel identification of fixed-length ATM cells facilitates implementation of flexible bandwidth allocation. The combined flexibility and capability of SONET, ATM, and photonic switching to serve adverse and demanding collection of various kinds of traffic opens up to final step to highspeed data traffic.

Traffic Descriptors

An ATM source sends ATM cell traffic to its corresponding ATM destination over the network. Traffic parameters are values that can specify the nature of the source traffic characteristics. A number of ATM attributes characterize the service categories. While setting up a connection on ATM networks, users can specify the parameters related to the desired quality of service. Traffic descriptors provide part of the connection related parameters like usage information, traffic type bandwidth requirement, and so on. The ATM forum has defined a number of descriptors that characterize the traffic pattern of ATM cells over an ATM connection.

The source characteristics of an ATM traffic flow are captured by the source traffic descriptor. This traffic descriptor describes the peak cell rate, sustainable cell rate, maximum burst size, and minimum cell rate. The maximum instantaneous rate at which the user will transmit is defined as peak cell rate (PCR). PCR is typically measured in cells per second. Sustainable cell rate is the average rate as measured over a long time interval. Maximum burst size (MBS) is a traffic parameter that specifies the maximum number of cells that can be transmitted at the ATM's PCR. MBS is a key measurement in capacity planning and network management. Burst tolerance (BT) determines the maximum burst size that can be sent at the peak rate conforming to the traffic contract. This is the measure of the time interval between consecutive bursts during which cells are sent at PCR. The characteristics of ATM flow over an ATM connection are captured in connection traffic descriptor.

Traffic Types

ATM is designed to handle a wide variety of traffic types. Several studies were conducted to address the issues of integrating different traffic sources. The B-ISDN traffic types can be categorized as follows.

Real Type Traffic

Traffic generated by voice and video sources have stringent performance requirements and are classified as type 0 traffic. The performance requirements are expressed in terms of delay, delay jitter, and cell loss.

Data Traffic

Traffic originating from data sources take the form of type 1, 2, or 3. A type 1 traffic is composed of low intensity traffic. This may consist of short burst of cells followed by long periods of relative inactivity. Type 2 traffic is made up of short file transfers between work stations and remote servers. Type 3 traffic moves large files between computers.

Service Categories

ATM virtual categories operate according to one of the following categories.

1. Constant bit rate
2. Variable bit rate
3. Unspecified bit rate
4. Available bit rate
5. Guaranteed frame rate

BROADBAND SIGNALING

Signaling is a technique whereby signals are used to exchange information or convey instructions to the remote machine. Signaling is used between a user and a network or between networks to exchange various control information. Signaling provides the functions such as the ability to establish point to multipoint connections, identification of virtual paths, recovery from network errors, and so on. The principal job of signaling is to establish, monitor, and release connections. The complexity of the signaling procedure depends on the flexibility provided by the network.

The year 1998 witnessed the emergence of signaling system seven (SS7) that provided the "out of band" common channel signaling capability. SS7 provided the signaling capability with which the users could specify quality of service (QoS) requirements. SS7 N-ISDN and B-ISDN are lower level capabilities that interconnect terminal equipment or service providers through local functional capabilities (ETSI 1998). SS7 provides out-of-band inter-exchange capabilities for telephony and N-ISDN. ATM SS7 interworking enables high-bandwidth ATM networks to integrate seamlessly with traditional circuit switched SS7 based digital telecommunications networks. Interworking between SS7 and ATM networks primarily involves signaling interworking, bearer service mapping, and traffic interworking, among other functions.

Signaling information traveling through the same virtual channel is called in-band signaling. Signaling information traveling through a different channel is called out-band signaling. The associated common channel signaling carries the signaling channels and the data paths through the same network elements. It is thus evident that the signaling channels closely follow the data paths. When the signaling channels do not share the same physical channel, it is then called as non-associated common channel signaling.

The control plane of B-ISDN handles all virtual connection related functions. This section provides an overview of B-ISDN UNI and NNI signaling protocols. Signaling

over the B-ISDN UNI is specified by ITU-T recommendation Q.2931. The service specific coordination function (SSCF) is defined by ITU-T recommendation Q.2130. ITU-T Q.2110 specifies the service specific connection oriented protocol. B-ISUP (N-ISDN user part-ISUP) is defined in Q.2761 to Q.2767. This is used for signaling between networks at an NNI. In support of the deployment of large-scale public ATM networks, Bellcore has issued a document, entitled "broadband switching system SS7 requirements using the broadband integrated services Digital Network User Part (B-ISUP) (Chang et al. 1995) to describe procedures for using the B-ISUP of SS7 to establish and release switch-to-switch virtual connections based on the ITU recommendation Q.2761-2764.

The signaling channel operates on VPI-0 and VCI-5 on a physical interface. There are two types of signaling channel configurations viz., the associated signaling and non-associated signaling. The associated signaling is deployed by UNI3.1. The Q.2931 recommendation defines a virtual path connection identifier (VPCI), which associates a signaling VCC with one or more VPIs. UNI4.0 and UNI4.1 defines non-associated signaling based on Q.2931.

ATM provides elaborate signaling support for dynamic establishment and release of switched virtual circuits (SVC). It assumes a greater significance in ATM due to the extensive traffic contracting and CAC mechanisms. The signaling procedures for ATM are defined for user network interface and network-network interface. The signaling information includes QoS parameters. The UNI interface is implemented in one of the two ways. The UNI can be a continuous stream of ATM cells clocked at a bit rate of 155.520 Mbps, or 622.080 Mbps.

Meta Signaling

A different signaling technique is metasignaling. ITU-T draft recommendation Q.2120 describes the meta-signaling protocol. This is used for establishing, maintaining, and removing user network connections at the UNI. This is a part of the ATM layer and is located within the management plane.

In the ATM layer, the meta signaling protocol will be specified based on the terminal endpoint identifier (TEI) allocation procedure in LAP-D (Q.921).

Meta signaling refers to the process of establishing channels using signaling procedures. Meta signaling sets up three types of signaling channels, viz. point-to-point, general broadcast, and selective broadcast. The following procedures are used for the meta signaling protocol viz. assignment, check and removal. The assignment, checking, and removal procedures are independent of each other. The necessary relationship between them is performed via plane management. The assignment procedure is invoked by the user side sending an ASSIGN request to the network. The check procedure is initiated by the network sending a CHECK REQUEST message and waiting for CHECK RESPONSE. The removal procedure is initiated either by the network side or by the user side.

Signaling AAL

ITU-T recommendation Q.2100 specifies the protocol model for signaling AAL (SAAL). The SSCS portion of SAAL is made up of service specific coordination function (SSCF) and service specific connection oriented protocol (SSCOP). SSCF provides services to signaling AAL. Q.2130 defines the SSCF for UNI and Q.2140 defines SSCF for NNI. SSCF provides a mapping between the simple state machine for the user and the state machine employed by service specific connection oriented protocol (SSCOP). SSCOP is a peer-to-peer protocol. Q.2110 defines the SSCOP for UNI and NNI. (See Figure 5.)

The SSCOP of AAL provides mechanisms for the establishment and release of connections and the reliable exchange of signaling information between signaling entities. It performs the following functions.

It preserves sequence integrity by preserving the order of SSCOP-PDUs. It provides ordered delivery, error correction by retransmission, flow control, and error reporting to layer management entities. It generates status reports between peer entities. It helps two peer entities to remain in connection during prolonged absence of data transfer.

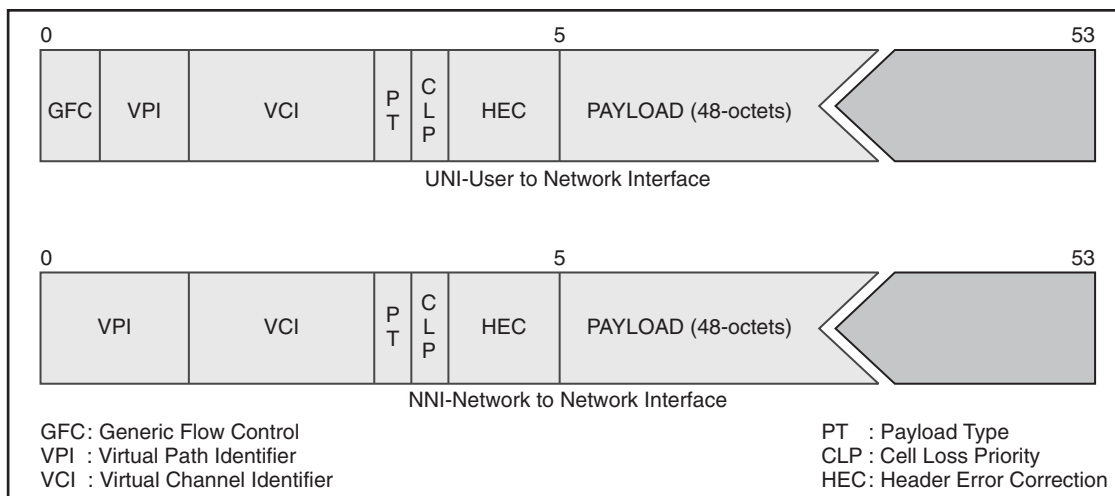

Figure 5: UNI-NNI

It provides local data retrieval, transfer of data, and link management functions. It is a fairly complicated protocol. The richness of SSCOP is in the assured data transfer mode. The SSCOP requires that the transmitter periodically poll the receiver as a keep alive action as well as a means to detect gaps in the sequence of successfully received frames.

Private Network Network Interface (PNNI)

PNNI protocol specifies interrelated routing and signaling protocols and functions to achieve the goal of controlling ATM connections established between nodes and connections. Version 1.0 of PNNI specification was released in 1996. PNNI is a routing protocol for ATM that allows for the exchange of routing information between ATM switches. Version 1.1 of the PNNI specification was released in 1996. It is an interesting standard and is less influenced by vendor competition. The PNNI protocol specifies interrelated and signaling protocols and functions to achieve the goal of controlling ATM connections established between nodes and networks. PNNI employs a recursive, hierarchical design that scales to huge networks. PNNI is the ATM routing protocol that enables switches to automatically discover the topology and characteristics of the links interconnecting the switches. PNNI uses UNI signaling to dynamically signal connection establishment and release request. PNNI identifiers uses the ATM end system address (AESA). AESA is derived from the international standards organization (ISO) defined in ISO/IEC8348 and specifies the formats, semantics, syntax, and coding of AESAs. The UNI specification specifies four AESA formats.

BROADBAND SERVICES

The services offered by telecommunications networks are increasingly diversified (Amin-Salehi et al. 1990). New service opportunities that address this trend in both residential and business environments extend beyond voice and low speed data applications. The service aspects of B-ISDN were jointly considered by CCITT SGI and SGXVIII. B-ISDN offers the flexibility to transport and switch a diverse range of services with bandwidth requirements from a few kbps to several Mbps. B-ISDN services are expected to have widely varying bandwidth, burstiness, and session length requirements. In response to the range of service requirements the B-ISDN design is based on high speed packet techniques. The broadband services are defined by ITU-T I.113 and I.211.

CCITT defines broadband service as a service requiring transmission channels capable of supporting rates greater than 1.5 Mbps or primary rate in N-ISDN or T1 or DS1 in digital terminology. Broadband and high-speed distribution services are characterized by long holding times and by constant bandwidth or constant bit rate.

Two families of data services are offered by ISDN (Day 1991). They are the circuit mode data services and packet mode data services. The circuit mode data services are offered by N-ISDN and accessed via the B channel based on the Q.931 setup and management procedures. The packet mode data services are further categorized as

packet switched data services accessed via D or B channel and frame switched data services via the B channel. The B-ISDN with the ATM transfer technique, offers the cell relaying services on top of which other data services are offered. ITU-T differentiates the services into interactive and distributed services. Each service can again be divided into a number of sub-services.

Conversational services are basically end-to-end, real-time communications, between users or between a user and a service provider. This service supports the transfer of data, specific to user application. The additional bandwidth offered will allow services such as video telephony, video conferencing, video surveillance and high-volume, high-speed data transfer.

Messaging services are not real-time services. They provide user-to-user communication through storage units and store and forward mailboxes. Applications could include voice and video mail, as well as multimedia mail and traditional electronic mail. This places lesser demands on the network.

Retrieval services provide access to (public) information stores, and information is sent to the user on demand. This includes services like tele-shopping, videotex services, still and moving pictures, tele-software, and entertainment.

Distribution services are broadcast services, intended primarily for one-way interaction from a service provider to a user. The user has no control over the presentation of the information. Unlimited number of authorized receivers receive the information. This would be, for instance, a TV broadcast.

Business and residential services It is also possible to classify the B-ISDN services into business and residential services. Though there is a promise from B-ISDN to provide all the above-mentioned services, it is a lot more difficult to achieve the defined objectives.

Video Services

Two types of video services have emerged viz., entertainment distribution services targeting the residential customers and retrieval services targeting the business and residential customers. Switched access television service the delivery of entertainment video to residential customers over switched facilities is a good candidate for a representative B-ISDN application.

B-ISDN permits switched access television (SAT). This has several advantages over the traditional distribution networks. SAT provides higher quality signals with increased selectivity. SAT also requires significantly shorter setup delays than telephony. It eliminates the need for scrambling equipment. The most important capability requirement for this application is a high-bandwidth downstream digital channel. The transmission requirements between the user and the switch in order to handle switched access television are determined by the bit rate requirements for each video channel and for the number of video channels needed.

Broadband End User Applications

The set of applications can be grouped into general purpose applications and special purpose applications. The

special purpose applications are the consumers of telecommunication bandwidth, super computers, high-speed workstations, and large data repositories interconnected for the purpose of processing medical images, molecular models, distributed CAD/CAM, geographical information services, and so on (Irvin 1993). As digital records are displacing paper records, applications such as backup and recovery, remote site storage, and distributed database update become increasingly important.

Connectionless services over ATM are being looked at with increasing interest and LAN to LAN interconnection. This service will be the first one to be offered in the B-ISDN together with the basic ATM bearer service, particularly in consideration of the fact that connectionless services may be offered efficiently over semi-permanent VP connections.

Another important class of application is multimedia combinations of text, image, speech, and music. This application includes distance learning, work-at-home, shop-at-home, electronic news paper, and electronic mail applications.

CONCLUSION

In the pre-ISDN era the data services available for PCs and PC network consist mainly of circuit switched data services and X.25 packet switched services. The development and standardization of B-ISDN, ATM, and signaling protocols for B-ISDN represent crucial elements in the evolution towards a multi service network. ATMs most important attribute is flexibility achieved through simplicity. N-ISDN and B-ISDN provide the overarching architecture for connecting CPE in a flexible, standard, and powerful manner. In a synergistic way, CPE and the public network are interlinked and each will provide an impetus for the other to evolve. Finally B-ISDN's ATM services meet the requirement of low-cost data transfer and connection time.

GLOSSARY

ATM Forum: The primary organization developing and defining ATM standards. Principal members participate in committees and vote on specifications

ATM layer: The layer of the ATM protocol stack that handles most of the processing and routing activities. These include building the ATM header, cell multiplexing, demultiplexing, cell reception and header validation, cell routing using VPIs/VCIs, payload-type identification, quality of service specification, and flow control and prioritization.

ATM management objects: (IETF RFC 1695) This specification defines objects used for managing ATM devices, networks, and services. ATM management objects allow net managers to consider groups of switches, virtual connections, interfaces, and services as discrete entities. The spec also specifies a MIB module for storing information about managed objects.

Constant bit rate (CBR): Digital information, such as video and digitized voice, must be represented by a continuous stream of bits. Such data gets transmitted

through the network by committing traffic at a constant rate.

Guaranteed frame rate (GFR): A proposed standard from the Traffic Management subworking group of the ATM Forum. GFR lets users specify a connection-dependent minimum cell rate for transmissions.

Maximum burst size (MBS): A traffic parameter that specifies the maximum number of cells that can be transmitted at ATM's peak cell rate (PCR). MBS is a key measurement in capacity planning and network management.

Metasignaling: The technique employed by the ATM user-to-network interface (UNI) to establish a virtual circuit (VC) that conveys signaling information about switched virtual circuits (SVCs).

Multi protocol over ATM (MPOA): A proposed ATM Forum specification that defines how ATM traffic is routed from one virtual LAN to another.

Peak cell rate (PCR): The maximum rate at which cells can be transmitted across a virtual circuit, specified in cells per second and defined by the interval between the transmission of the last bit of one cell and the first bit of the next.

Physical layer (PHY): The bottom layer of the ATM protocol stack, which defines the interface between ATM traffic and the physical media.

Private network-to-network interface (PNNI): A routing information protocol that allows different vendors' ATM switches to be integrated in the same network.

Synchronous optical network (SONET): An international suite of standards for transmitting digital information over optical interfaces. "Synchronous" indicates that all component portions of the SONET signal can be tied to a single reference clock.

NEED FOR DIGITAL SUBSCRIBER LINE What Is DSL?

The telephone network was originally designed to carry speech signals. The bandwidth needed for voice transmission is approximately 3.6 kHz from 0.406 to 4 kHz. Through various modulation techniques, it is possible to transmit data signals in the voice band. A number of standards ranging from V.21 to V.90 have been published dealing with data transmission over the voice band with each successive standard enabling a higher data rate.

Digital subscriber line (DSL) technologies use the bandwidth of the twisted-copper pair lines beyond the voice band (0.406–4 kHz) used by the voice telephone services. The DSL bridges what is commonly called the “last mile” (Goralski 1999) to the optical fiber deployed in the neighborhood by telecommunication companies. The DSL and voice band modems provide a dedicated link from the customer’s premises to the central office, that is, a one-to-one connection. Although thought of as an interim solution until the full fiber deployment, DSL will be of interest for a number of years as the deployment of the direct optical fiber link has been slow and limited to urban areas (Henkel, Ölçer, Jacobsen, Saltzberg, and Bush 2002).

According to Mueller (2006), there were 209.3 million broadband subscribers worldwide at the end of 2005, which was an increase of 37% since the end of 2004. In the United States and China together, the number of DSL lines exceeded 40 million at the end of 2005. Adding the cable modem deployment numbers in those two countries brings total deployment to around 80 million at the end of 2005 (Mueller 2006). Mueller also finds that worldwide, the DSL share of broadband access stands at 66.2 percent, cable share at 24.29 percent, with the rest provided by the optical fiber. The largest number of lines is installed in the Asia-Pacific region (mostly China, South Korea, and Japan). The reason for the DSL success in Korea can be found in the high population density in urban centers collected around large apartment complexes. According to Lee and Lee (2003), the number of households with

broadband access surpassed 70 percent and Korea Telecom alone has 5.4 million DSL users.

Broadband Access Model and Applications

Figure 1 shows the broadband access network model. Customer premises are connected to the network through a twisted-copper pair. At the customer premises, a splitter separates the broadband signal and the voice band. At the central office side, the voice service connects to the telephone network, whereas the broadband signal goes through the DSLAM (the figure is simplified as it does not show the multiplexing of many lines in the DSLAM module) and the ATM (or the IP router) switch to the Internet.

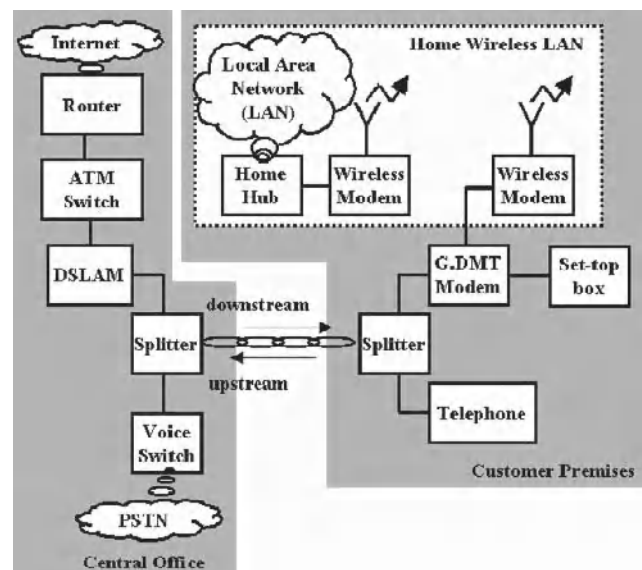

Figure 1: Block diagram of digital subscriber line broadband access (DSLAM, digital subscriber line access multiplexer, PSTN, public switched telephone network, DMT, discrete multitone modulation, ATM, asynchronous transfer mode, ISDN, integrated services digital network)

Table 1: Data Rate Requirements of Various Applications

Application	Downstream Rate(kb/s)	Upstream Rate (kb/s)	Demand Potential
Database Access	384	9	Medium
On line Directory; Yellow Pages	384	9	High
Video Phone	1,500	1,500	Medium
Home Shopping	1,500	64	Medium
Video Games	1,500	1,500	Medium
Internet	3,000	384	Medium
Broadcast Video	6,000	0	High
High Definition TV	24,000	0	Medium
Remote Office	6,000	1,500	Low
Office LAN	10,000	10,000	Medium
CAD	45,000	45,000	Low

Table 1 shows some of the applications driving the deployment of DSL technologies along with the data rates necessary to support their use. Although some DSL technologies are able to satisfy some of the data rate and loop reach requirements, none is able to satisfy all of them.

A survey of Internet access in Korea by the Korea Network Information Center (2003) notes that users primarily use email, games, Web surfing, and chatting. So, broadband access (nearly universal in Korea) allows faster use of these applications and does not, as of yet, facilitate high bandwidth applications such as streaming video or videophones.

DSL versus Other Technologies

Cable: *The Economist* (2003) writes that the U.S. local telephone carriers lose telephony customers at a rate of 5 percent to 6 percent per year to cable broadband access. Fitchard (2003) suggested that the market share for broadband services in the United States at the end of the third quarter of 2002 was 2:1 in favor of cable modem access over DSL. The number of United States households in 2001 with access to the cable network (not necessarily subscribers) was estimated at 99 million (Dutta-Roy 2001).

The coaxial cable TV infrastructure provided fertile ground for the development of a technology that multiplexes various types of content delivered over the same coaxial cable. Now cable providers offer cable TV services including TV interactive service, access to the Internet, VoIP, "always-on" service at connection speeds up to 5 Mbps, and video-on-demand. The disadvantage of cable is that it is a shared medium; that is, all users have to share the available bandwidth in contrast to a dedicated DSL line.

The Multimedia Cable Network System (MCNS) consortium began cable standardization in 1995 by producing Data Over Cable Service Interface Specification (DOCSIS) standards with versions 1.0 approved by the International Communications Union in 1998 and 1.1 approved in 1999.

DOCSIS 1.1 improved upon DOCSIS 1.0 mainly in the area of quality of service (QoS) with the intent to enable VoIP (Lankford, Gameel, Boras, Cheema 2001). DOCSIS 2.0 was approved in December 2002 and adds greater upstream bandwidth, trellis-coded modulation (TCM) and an additional multiple access technology in code division multiple access (CDMA) besides time division multiple access (TDMA). The data rate available in DOCSIS 2.0 standard over a single downstream 6.4 MHz channel is approximately 30.7 Mbps (shared) and 1.5 Mbps upstream over a single upstream channel. Research based on statistical models cited in Dutta-Roy (2001) predicts that up to 400 households can be connected to a single 6.4 MHz channel without traffic congestion caused by the shared cable medium. The downstream is based on the 64-QAM modulation where each symbol carries 6 bits (optional TCM turns the 64-QAM into the 128-QAM to accommodate the extra bit for TCM). The upstream uses the 16-QAM where each symbol carries 4 bits. The choice of a smaller modulation signal set for upstream was dictated by the higher noise present in the upstream frequency band as a result of the interference from poorly terminated subscriber equipment, household appliances, and strong radio transmitters (Powell 1996). This was not of concern in the low data rate mode of interactive cable TV service using the upstream frequency band (Temple 1999; Hendry 1999). However, it has become a concern for the cable modem technology, which uses the upstream band at a much higher data rate.

Wireless: Wireless technologies are competing with DSL and cable for broadband access market. In 2005 Verizon Wireless began a wireless broadband service based on 3G CDMA with access rates of 400 to 700 Kbps. This broadband service is available in major metropolitan areas in the United States and allows seamless switching between the Verizon's wireless broadband and cellular networks when the user leaves the broadband coverage area (Krakow 2004). Wireless broadband access offers VoIP and Internet access.

Table 2: DSL technologies (NA, North America; E, Europe; DS, downstream; US, upstream; Pairs, number of twisted-copper pairs; PAM, pulse amplitude modulation; 2B1Q, two bit per quaternary symbol; 3B1O, three bits per symbol; DMT, discrete multitone modulation)

DSL	Modulation	Data Rates	Bandwidth	Pairs	Distance
HDSL	2B1Q (4-PAM)	1544 kbps (NA) 2048 kbps (E)	193 Hz <580 kHz	2 3	12000 ft
G.991.2 SHDSL	3B1O (8-PAM) trellis-coded PAM	192 kbps 2312 kbps 4624 kbps	1.5 MHz	1 1 2	18000 ft
G.992.1 ADSL	DMT 256 tones	6144 (8192) kbps DS 786 (640) kbps US	1104 kHz	1	18000 ft
G.992.2 ADSL Lite	DMT 128 tones	1536 kbps DS 512 kbps US	552 kHz	1	25000 ft
G.992.3 ADSL2	DMT 256 tones	ADSL + 50 kbps Can group >1 pair	1104 kHz	1	18600 ft
G.992.5 ADSL2+	DMT 256 tones	25 Mbps DS 1 Mbps US	2208 kHz	1	3000 ft
G.993.1 VDSL	DMT 4096 tones	52 Mbps DS 3 Mbps US	12 MHz	1	3000 ft

The telephone companies are upgrading their telephone copper network to achieve higher data rates and enable services with higher entertainment value. DSL allows telephone companies to use their twisted-pair based network to offer VoIP, TV, and high-speed Internet access and to compete with the cable and wireless broadband access.

DSL STANDARDS

Overview

The predecessor of DSL is the physical layer of ISDN (integrated services digital network) developed in the 1980s for distances of up to 18,000 ft (ANSI 1992). ISDN offers two types of services: the basic rate interface (BRI) and the primary rate interface (PRI). The BRI has two B-channels (carrying user data at 64 kbps) and one D-channel (control signaling at 16 kbps) for a total of 144 kbps. The PRI has 24 B-channels and one D-channel (at 64 kbps) in Japan and North America for a total of 1.544 Mbps (with overhead bits), whereas other parts of the world offer 30 B-channels for a total of 2048 Mbps (with overhead bits). Following ISDN was the development of the high-bit-rate DSL (HDSL) (ITU-T 1998) at 1.544 kbps with the same signal processing techniques as ISDN. Single-pair HDSL (SHDSL) (ITU-T 2003b) is a version of HDSL over a single wire pair. Asymmetric DSL (ADSL) (ITU-T 1999) was standardized in 1995 and enjoys a rapid increase in worldwide deployment. ADSL uses the bandwidth of up to 1.1 MHz and achieves 6144 kbps downstream and 640 kbps upstream. ADSL2 (ITU-T 2002) improves on the reach and the rate adaptation of ADSL, whereas ADSL2plus (ITU-T 2003a) doubles the bandwidth used to 2.2 MHz. ADSL2 with the inverse multiplexing for ATM (IMA) standard allows bonding of several physical layer links from a single user thus,

allowing multiplication of data rate (ADSL Forum 2003). A very-high-speed DSL (VDSL) (ITU-T 2004) is intended to bridge short copper access line lengths (shorter than 3000 ft) at high speeds ranging up to 22 Mbps from the network to the residential customer. Table 2 summarizes the specifics of different DSL technologies. Both the reach and the data rate vary as the technologies were developed for different applications.

Figure 2 shows the spectral allocation of different DSL services. Bandwidth allocated to different services is determined based on the desired data rate of the service, desired reach, and the presence of existing services and their mutual interference. For a detailed exposition on the DSL historical development, see Chen, 1998 and Starr, Cioffi, and Silverman, 1990.

SUBSCRIBER LOOP AND NOISE ENVIRONMENT

Bridge Taps and Loading Coils

The twisted-pair between the central office and the customer premises may have branching connections so that additional customers can be served or additional telephones can be connected at the customer premises. These branching connections are called “bridged taps” (Chen 1998, 20–21; Starr, Cioffi, and Silverman 1999, 57–58) and are connected to the cable on one end and usually un-terminated on the other. These branches cause attenuation and distortion as a result of the signal reflections from the un-terminated end. The distortion results from the spreading of the channel impulse response as a result of the multiple signal reflections. The attenuation is the result of signal cancellation caused by out-of-phase reflection from a bridge tap of a length matching the quarter-wavelength of a particular signal frequency. This results in deep

Figure 2: xDSL spectral allocation

notches in the frequency response of the system. These impairments are partly mitigated by the use of adaptive equalizers, echo cancellers, and time guard bands between symbol transmissions. Often, telephone lines in excess of 15,000ft include loading coils. The coils decrease the attenuation in the voice band and extend the reach of voice service. However, these coils simultaneously increase the attenuation in the frequencies beyond the voice band and make it impossible to have a DSL connection. These coils have to be removed from the phone lines when a DSL connection is desired, thus, they have been removed in many countries as a result of the DSL deployment.

Transfer Function of the Twisted-Pair Transmission Channel

The twisted-pair lines can be modeled using the two-port ABCD matrix. The transfer function of a twisted-pair of any length can be calculated by cascading the appropriate number of unity cable sections that are represented using their ABCD parameters. The voltages and currents present at the cable are defined using the source (port 1) and load (port 2) impedances according to $\begin{bmatrix} V_1 \\ I_1 \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} V_2 \\ I_2 \end{bmatrix}$ in

which A is the open-load voltage ratio $A = \left. \frac{V_1}{V_2} \right|_{I_2=0}$, B is

the short-load impedance $B = \left. \frac{V_1}{I_2} \right|_{V_2=0}$, C is the open-load

admittance $C = \left. \frac{I_1}{V_2} \right|_{I_2=0}$, and D is the short-load current

ratio $D = \left. \frac{I_1}{I_2} \right|_{V_2=0}$. For a detailed coverage of the ABCD

modeling see Starr, Cioffi and Silverman, 1999 and Chen, 1998.

Noise Sources

The main source of crosstalk in DSL systems is the crosstalk from other DSL systems. Crosstalk is the current induced in neighboring wires by the electric and magnetic fields of the source. Twisted pairs are designed to minimize the electromagnetic coupling by twisting the wire so that currents of opposite directions cancel the induced signals. However, as a result of wiring imperfections, some energy leaks into the neighboring pairs as a source of noise. Figure 3 shows the near-end crosstalk (NEXT), far-end crosstalk (FEXT), and near-end echo. The NEXT is caused by a transmission of a signal traveling in the opposite direction compared to the desired signal. The NEXT transmitter is generally physically close to the receiver. A far-away transmitter transmits the FEXT, which travels in the same direction as the desired signal and traverses the length of the cable. In cases when a 4-to-2 wire interface (called hybrid circuit) is present and when a simultaneous transmission and receptions of signals on the same twisted pair is intended, the receiver may experience near-end echo. Echo is the signal from the local transmitter that leaks into the local receiver as a result of the imperfections of the hybrid circuit.

The FEXT power spectral density at the input to a DSL receiver is modeled by the $PSD_{FEXT}(f) = 9 \times 10^{-20} \times S(f) \left(\frac{N}{49} \right)^{0.6} d \times f^2$ in which $S(f)$ is the power spectral density of the noise source, d is the length of the cable in

feet, f is frequency in Hz, and N is the number of disturbers. The PSD_{FEXT} grows with the square of the frequency but only linearly with the length. The PSD_{NEXT} at the input of a DSL receiver is modeled by the

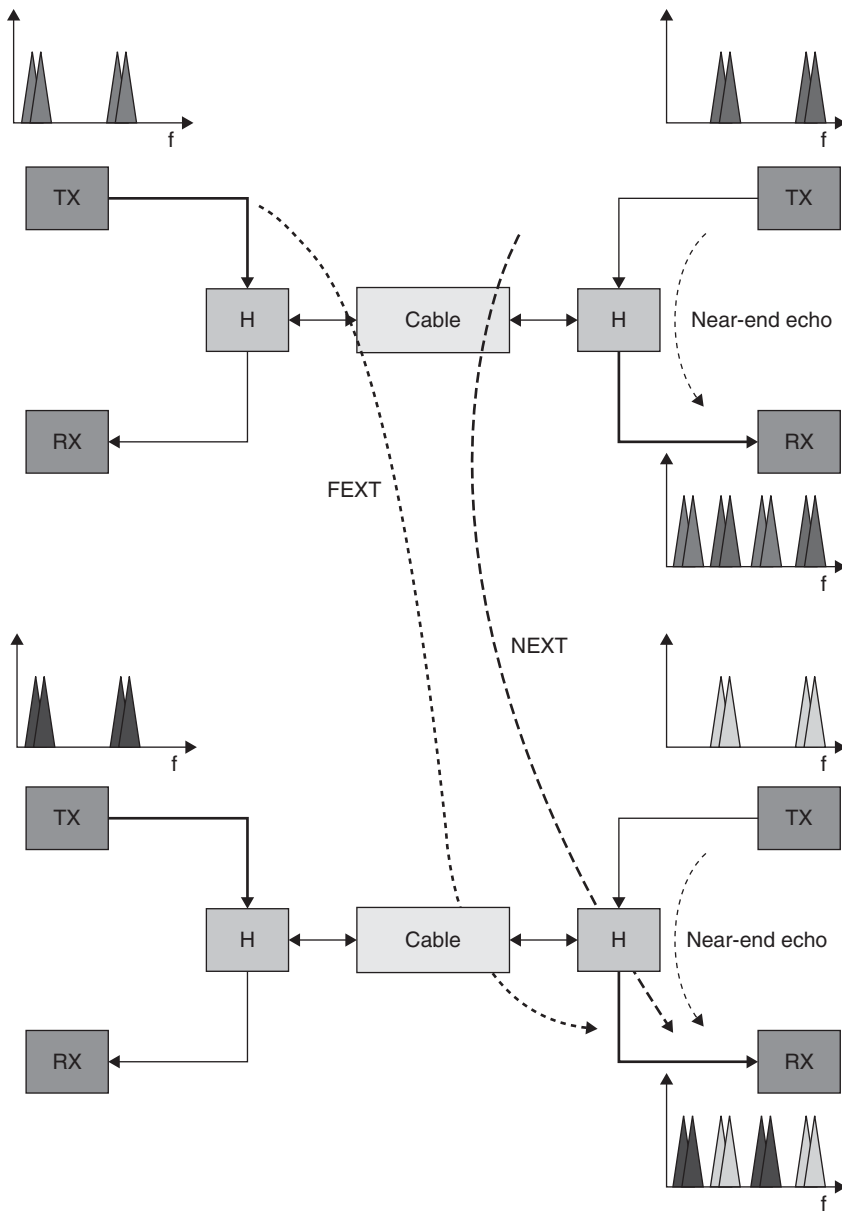

Figure 3: Near and far-end crosstalk

$$PSD_{NEXT}(f) = S(f) \left(\frac{N}{49} \right)^{0.6} \frac{f^{1.5}}{1.134 \times 10^{13}} \text{ in which } S(f) \text{ is}$$

the power spectral density of the noise source, f is the frequency in Hz, and N is the number of disturbers.

HDSL Applications

High bit rate DSL (HDSL) was developed as a replacement technology for the T1/E1 transmission systems. In October 1998 ITU approved G.991.1 (ITU-T 1998) HDSL modeled closely after the ETSI TM-03036. An amended version was approved in 2003. The second generation of HDSL, known as single-pair HDSL (SHDSL) (not to be confused with pre-standard implementations known as symmetric DSL) uses only one pair of wires instead of two to achieve variable 192 kbps to 2.312 Mbps payload.

SHDSL reaches 18,000 ft without repeaters because its transmit power is 3 dB higher than the one for HDSL and the use of trellis-coded modulation. The improvement over HDSL is also found in the transmission spectral mask that was designed to reduce the crosstalk to other communication technologies.

HDSL is used to connect users requiring T1/E1-like data rates to central offices at a lower cost, with better reliability, and a higher maintainability than it is possible with T1/E1 systems. HDSL operates at 10^{-7} or better bit error rate. As Starr et al. (1999) mention, HDSL will operate at 10^{-7} under worst-case conditions, whereas 99 percent of the links operate at 10^{-9} or better. The T1/E1 systems were designed in the 1960s to carry traffic in between central offices (CO). The T1 achieves 1.544 Mbps using the alternate mark inversion (AMI) line code, whereas the E1 achieves 2.048 Mbps using HDB3. The T1/E1 systems are not used anymore as the high-speed links between central offices as

fiber and microwave links have replaced them. The T1 systems are expensive to install because they require repeaters and they need to be congregated into binders where the lines carrying data to the customer are in one binder and the lines carrying data from the customer are in another (the T1 systems use four wires for communication). HDSL was developed as a low-cost alternative to the T1 as it did not require repeaters up to the loop length of 12,000 ft and no binding or loop conditioning apart from the elimination of loading coils. For the customers living beyond the 12,000 ft limit, HDSL systems are deployed using a single repeater to reach 24,000 ft or with two repeaters to reach up to 36,000 ft. HDSL also brought more advanced loop and traffic diagnostic capabilities compared to the older T1/E1 systems. As the HDSL was intended to replace the T1/E1 lines, it supports the communication over two or three pairs of wires for a data rate of 1.544 Mbps matching the T1 and 2.048 Mbps matching the E1. Each pair uses full-duplex communication with 784 kbps net and 768 kbps payload in each direction. It is common to use the term dual-duplex for two-pair HDSL and fractional-rate HDSL for each of the pairs. The dual-duplex uses echo cancellation to separate two directions of transmission, which occupy the same frequency band. The fractional-rate HDSL carries up to twelve DS0 (Digital Signal 0) channels and connects to a D4 channel bank, which multiplexes DS0 channels from multiple fractional-rate HDSL channels.

Line Code

The two-pair HDSL 3 dB bandwidth is 196 kHz and the symbol rate is 392 ksym/s, thus the data rate per wire pair is 784 kbps. HDSL uses a line code known as 2B1Q (4-PAM), which maps two bits of information into one quaternary symbol. SHDSL uses 3B1O modulation, which maps three bits of information into one symbol. The 2B1Q is a baseband code, that is, it contains a DC component. Figure 4 shows the HDSL time domain transmitted pulse mask.

The transmitted pulse is distorted by the transformers present in an HDSL circuit, which do not pass the DC and by the band-limited channel with varying frequency

domain response over the transmission frequency band. The receiver uses equalizers to eliminate the effects of the channel. The mapping of two bits to symbols used in the 2B1Q is called Gray coding and it ensures that a decoding error would result in only one bit error.

ADSL Applications

According to Chen (1999) the goal of arriving at the asymmetric digital subscriber loop (ADSL) standard was to promote the technology that was to serve economically subscribers at distances of up to 18,000 ft (from the CO) with the T1 rates of at least 1.544 Mbps over a single twisted-copper pair. Reusens et al. (2001) wrote that the original intent for the ADSL was video-on-demand (VoD); however, that application never succeeded as a result of a lack of a business case for it. Bingham (1990) argues that although the idea of multicarrier modulation has been present for many years, the signal processing power has enabled its use over telephone cables in the 1990s. The ADSL was standardized in the United States by the American National Standards Institute (ANSI) T1.413–1998 (1998), and internationally by the International Telecommunications Union G.DMT (G.992.1) (1999), G.Lite (G.992.2) (1999), ADSL2 G.992.3 (2005), and ADSL2 + G.992.5 (2005). The G.DMT reaches up to 18,000 ft and provides the uplink rate of up to 8,192 kbps and a downlink rate of up to 640 kbps.

Line Code

The G.992.1 ADSL is full duplex, that is, data simultaneously flows downstream from a central office to a remote terminal, and upstream in the opposite direction on a single twisted-wire pair. The ADSL uses discrete multitone (DMT) as a multicarrier modulation method in which the available bandwidth of a communication channel, such as twisted-pair copper media, is divided into numerous sub-channels or bins via a fast Fourier transform (FFT). In the G.992.1 ADSL standard, an FFT/IFFT block is used to generate up to 256 separate 4.3125kHz wide

Figure 4: HDLSL time domain transmit pulse (A, B, C, D, E, F, G, H are normalized signal levels where B maps to $\pm 2.625V$ for the ± 3 (10, 00) quaternary symbol and into $\pm 0.875V$ for the ± 1 (11, 01) quaternary symbol)

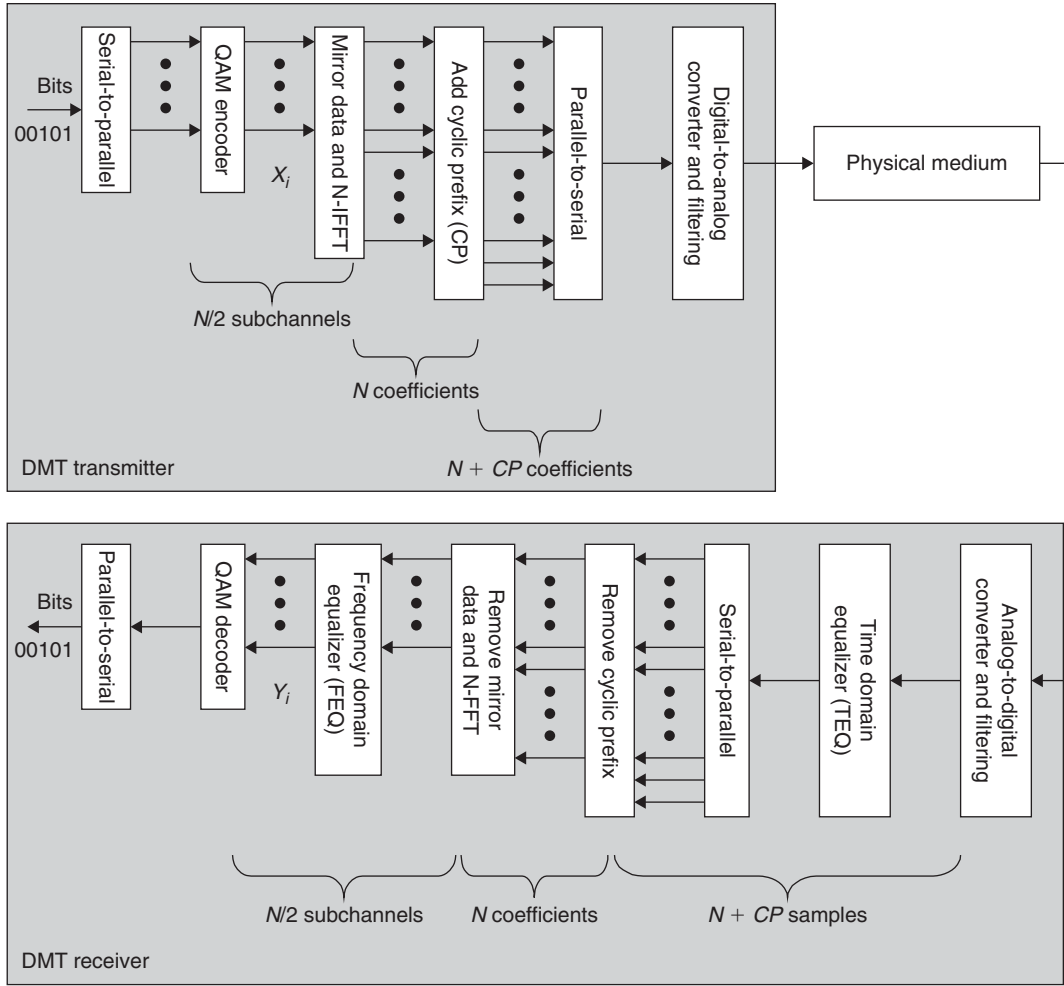

Figure 5: DMT transmitter and receiver

downstream sub-channels from 0 to 1.104 MHz. The ADSL uses the frequency band from 25.875 kHz to 1.104 MHz. Likewise, an FFT/IFFT block is used to generate 32 upstream sub-channels up to 138 kHz. Sub-channels in the range 0 to 25.875 kHz are not used in the ADSL so as not to interfere with the voiceband channel (0.406–4 kHz). The compatibility with the ISDN service is achieved by mandating lower transmission power in the frequency band 50 to 80 kHz for the 2B1Q ISDN or band 70 to 90 kHz for the 4B3T ISDN. Each DMT sub-channel is nearly independent of the other sub-channels and the degree of independence increases with the number of sub-channels (Cioffi 1991). Figure 5 shows a simplified block diagram of a DMT transceiver.

The input bit stream on the transmitter is mapped using quadrature amplitude modulation (QAM) into a $N/2 \times 1$ complex vector X_i at time i . The bit stream is partitioned, mapped into complex values and assigned to sub-channels based on the available SNR in each sub-channel and the desired bit error rate (10^{-7}). Vector X_i is mirrored into its conjugate-symmetric copy X_i^* and both are presented at the input of the IFFT block. An inverse fast Fourier transform (IFFT) block modulates each input entry into a different frequency band (sub-channel) with the carrier frequency lying in the center of the band.

The real-valued vector x of size N is defined using the IDFT as $x_k = \sum_{i=0}^{N-1} X_i e^{j \frac{2\pi k i}{N}}$ $k = 0, 1, \dots, N-1$. A guard

period of CP samples is added before digital-to-analog (D/A) conversion and transmission. A spectrally shaped channel impulse response longer than $CP + 1$ causes inter-carrier interference (ICI) and inter-symbol interference (ISI). The ISI refers to the mixing of energy belonging to neighboring symbols during transmission, whereas the ICI refers to a similar process for the sub-channels. If the length of the channel impulse response is less than or equal to $CP + 1$, then adding a guard period of CP samples at the beginning of a DMT frame will prevent the occurrence of the ISI. If the guard period is chosen to be the copy of the last CP samples of a DMT frame and the length of the channel impulse response is less than or equal to $CP + 1$, then the ICI is eliminated as well. This choice of the guard period is also known as a cyclic prefix. This grouping of $N + CP$ samples is referred to as a frame. Frames are sent sequentially one after the other. The CP additional samples lower the data rate by a factor of $N/(N + CP)$.

For the ADSL downstream transmission, $N = 512$ and $CP = 32$ samples, whereas for the ADSL upstream

transmission, $N = 64$ and $CP = 4$ samples. The receiver performs analog-to-digital (A/D) conversion, equalization using time-domain equalization (TEQ) using a finite impulse response (FIR) filter, CP elimination, FFT, QAM decoding, and error correction. The TEQ is designed during modem initialization and it shortens the impulse response to $CP + 1$ or less. A large number of research publications deals with the design of the TEQ; for a list of relevant publications see Milosevic, 2003.

The demodulation of the received DMT frame is done by the FFT block, after which the frequency domain equalizer (FEQ) completely removes the phase and frequency distortion of the channel. This fully equalized signal is then decoded using a QAM decoder resulting in an estimate of the transmitted complex symbol Y_i and further resolved into the corresponding bit stream. The data rate in bits per frame in the k th sub-channel is $b_k = \log_2 \left(1 + \frac{SNR_k}{\Gamma} \right)$

in which the difference between channel capacity and the best achievable rate in practice can be characterized by the SNR gap $\Gamma = 9.8 + \gamma_m - \gamma_c$ in which in the G.DMT ADSL, typically, for the probability of error 10^{-7} , $\gamma_m = 6$ dB, and $\gamma_c = 4.2$ dB; hence, $\gamma = 11.6$ dB and SNR_k is the signal-to-noise power ratio in the subchannel k .

The major noise source faced by the ADSL is the crosstalk from other the T1/E1, the SHDSL, and the HDSL. Ouyang, Duvaut, Moreno, and Pierrugues (2003) state that the low frequencies of the upstream channel are impaired by the noise from the SHDSL. The noise from other ADSL lines becomes the dominant factor on lengthy connections because of the superior reach of the ADSL over other services (Ouyang et al. 2003).

VDSL

Applications

The need for the VDSL is driven by high-data rate applications such as high-speed Internet access with requirements for high download speeds, multi-user high bandwidth access, high-definition TV (HDTV), high-quality video conferencing, and video-on-demand. The VDSL could also aid more specialized activities such as remote publishing, movie editing, engineering using remote CAD connections, and remote medical procedures.

ITU-T Recommendation G.993.1 VDSL was prepared by the ITU-T Study Group 15 and approved in 2004. The VDSL uses copper wires previously designed for telephone voice traffic and it exploits the bandwidth of up to 12 MHz. G.993.1 is full duplex, that is, data simultaneously flows downstream from a central office to a remote terminal, and upstream in the opposite direction. Figure 6 shows the

broadband access model of the VDSL in which the fiber from the service provider reaches into the neighborhood and terminates at the optical network unit (ONU).

This model is called “fiber-to-the-cabinet” and it allows the service provider to shorten the distance that the broadband signal will travel over the copper wires. The maximum distance that the signal will experience is up to 5,000 ft, which reduces the attenuation of the signal at the receiver compared to the ADSL and allows the VDSL to use the bandwidth of up to 12 MHz with correspondingly higher data rates compared to the ADSL (ADSL2), which uses up to 1.1 MHz (2.2 MHz). G.993.1 transceivers employ a frequency division duplexing (FDD) scheme to separate the upstream and downstream directions of transmissions. The G.993.1 FDD uses four bands starting from 138 kHz and ending at 12 MHz. The bands are denoted as optional, DS1, US1, DS2, and US2 with the spans shown in Figure 7 and Table 3.

The upstream and downstream bands are interlaced so that the VDSL connection can be established up to the specified length of the cable even though the attenuation of the cable may render bands DS2 and US2 unusable. The optional band usage and direction of transmission are determined during the initialization of the VDSL link. The start and end frequencies of the bands are determined by the bandplans specified in the standard. The bandplans are incorporated in the standard in order to accommodate regional specificities of national networks.

Line Code

The VDSL uses DMT as a multicarrier modulation method. The number of subcarriers will be equal to $N = 2^{n+8}$ in which $n = 0, 1, 2, 3$, or 4, thus the minimum number of tones is 256, whereas the maximum number is 4096. The exact number of tones used will be negotiated between the customer’s modem (VTU-R) and the CO modem (VTU-C) during the initialization stage. The bandwidth occupied by each tone is 4.3125 kHz with the carrier centered in the middle of the tone band. Real-valued samples will be generated from complex-valued vector X of length $2N$ via the inverse discrete Fourier transform (IDFT), in which the last N complex values are a conjugated mirrored image of the first N complex values. A value of zero is placed at the DC and at the Nyquist

Figure 7: VDSL spectral allocation

Figure 6: VDSL access network

Table 3: VDSL bandplans

	Bandplan (MHz)		
	A	B	C
Optional	0.025–0.138	0.025–0.138	0.025–0.138
DS1	0.138–3.75	0.138–3.0	0.138–2.5
US1	3.75–5.2	3.0–5.1	2.5–3.75
DS2	5.2–8.5	5.1–7.05	3.75–variable
US2	8.5–12	7.05–12	variable–12

frequency as no data is transmitted ever on those bands. The real-valued frame x of size $2N$ is defined using the

$$\text{IDFT as } x_k = \sum_{i=0}^{2N-1} X_i e^{j \frac{2\pi k i}{2N}} \quad k = 0, 1, \dots, 2N-1.$$

The last L_{cp} samples of x are pre-pended to it as a cyclic prefix, whereas the first L_{cs} samples of x are appended to it as a cyclic suffix. The first B and the last B samples of the cyclic prefix and cyclic suffix are shaped (multiplied by a suitable window such as raised cosine), in which B is equal to 2^{n+4} where n is at most 3. The shaped portions of successive frames overlap. The sum of cyclic extensions is $L_{cp} + L_{cs} - B = m \cdot 2^{n+1}$ in which m is an integer. The purpose of pulse shaping is to reduce the leakage of energy from one frequency band to another (Isaksson and Mestdagh 1998). This reduces the self-NEXT where the crosstalking transmitters are not synchronized to the receiver DMT frames and it also reduces out-of-band energy into protected radio bands.

Although the uplink and the downlink transmissions are separated into different frequency bands, the fact that parts of successive self-NEXT frames are captured will lead to some leakage of downlink energy into the uplink band. This is because of the transition between the cyclic suffix of one frame and the cyclic prefix of another (Figure 8).

Thus, to make these transitions less rapid and reduce the out-of-band energy compared to the ADSL standard, the VDSL standard imposes the shaping of the first and last B samples of a frame. This offers protection against NEXT, but it also decreases the throughput and increases latency as a result of the additional samples. In addition, VDSL receiver designs also employ windowing of the received $2N$ samples of a DMT frame to reduce the radio-frequency ingress (Isaksson and Mestdagh 1998).

The VDSL standard makes optional synchronous operation where all transmitters in a bundle start the frames at the same time or asynchronous operation when that is not the case. The VDSL specifies that all modem pairs in the same binder in synchronous operation will have the same length of the non-overlapped cyclic suffix and that length will be equal to the one-way propagation delay of the longest line in the binder. Because the cyclic suffix of a self-NEXT frame last as long or longer than the one-way propagation delay of this particular transmitter-receiver, one and only one DMT frame from a NEXT transmitter is captured along with the far-end signal in the received frame (Figure 9).

This eases the removal of the self-NEXT as it remains orthogonal to the far-end signal because of the frequency division duplexing (FDD) scheme that makes upstream and downstream occupy different frequency bands.

The VDSL (and ADSL) uses Reed Solomon (RS) codes for forward error correction (FEC) coupled with interleaving. The VDSL distinguishes between the “fast” and “slow” channel. Both channel’s data are protected using the RS code but the fast channel data is not interleaved, whereas the slow channel data is. The fast buffer gets its name because of its lower delay as a result of a lack of interleaving. The number of redundant bytes in the fast channel can be 0, 2, 4, or 16, whereas for the slow channel the value is set to 16. The VDSL encodes a stream of bits into symbols of constellations with 2^M points where $M = 1$ to 8 (15 in ADSL). The DMT modulation has a high peak-to-average ratio (PAR) and clipping is likely.

The fast buffer data is placed by into tones with lower signal-to-noise ratios (assigned smaller constellations), because impulse noise, for example, clipping noise, affects these tones less (the noise in these tones is already

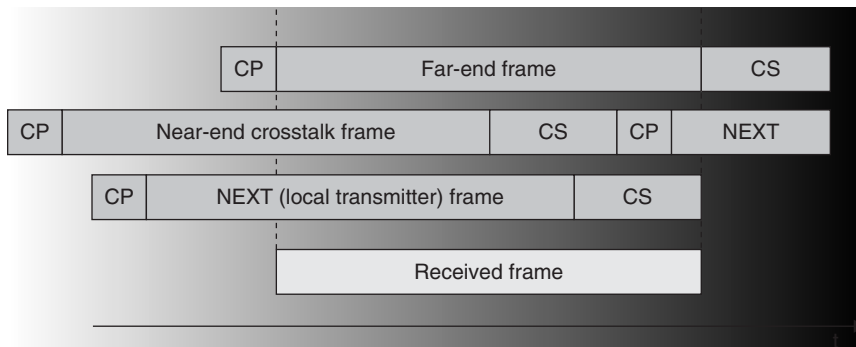

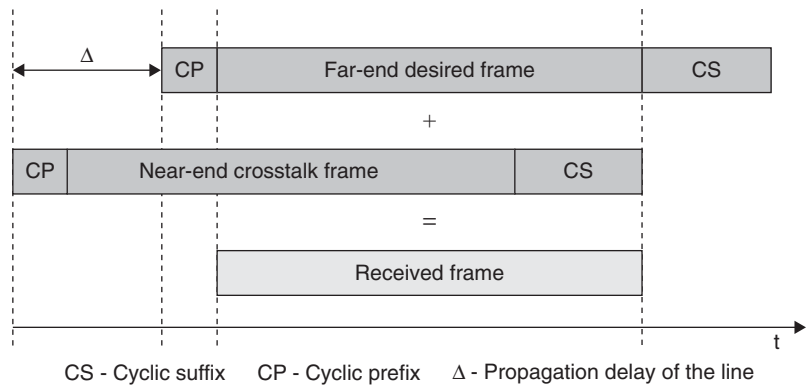

Figure 8: Misalignment of far-end and near-end DMT frames with more than one near-end crosstalk frame being captured at the receiver

Figure 9: Misalignment of far-end and near-end DMT frames with only one near-end crosstalk frame being captured at the receiver

high). The slow buffer tones are put in higher signal-to-noise ratio sub-channels because they are protected against an impulse noise by the interleaved RS code. The bits at the receiver are reconstructed into fast and slow buffers thus, reversing the procedure. The VDSL introduces the concept of power back-off where the far-end upstream transmitters reduce the transmit power to allow the nearby downstream receivers to establish a link.

CONCLUSION AND FUTURE DEVELOPMENT

Telecommunications providers are striving to provide universal broadband connectivity 24/7, at home, at work, at school and on the road (i.e., via mobile phones). The highest data rates are provided by optical fiber technologies. However, fiber deployment is expensive and in the interim alternative technologies are useful. The xDSL has grown tremendously in popularity over the last few years. Along with the increase in computational power of digital signal processor, the telephony broadband access technology progressed from the ISDN to the HDSL, the ADSL, and the VDSL offering ever-increasing access data rates to the consumers. Today, telephone companies compete with cable and wireless broadband technologies to provide access to television, data, and voice services over DSL lines. The market share of xDSL will continue to depend on the data rates achieved, quality of service, and the number of services that the customers can get from a single provider.

GLOSSARY

ADSL: Asymmetric digital subscriber line; a type of telephony lines broadband technology; asymmetric data rates with upstream rates higher than downstream; standardized in 1999 by ITU-T G.992.1.

ADSL2+: A version of ADSL standardized in 2005 by ITU-T G.992.5; doubles the bandwidth used from ADSL's 1.1 MHz to 2.2 MHz.

ANSI: American National Standards Institute.

DFT: Discrete Fourier transform; used in signal processing to analyze spectral content of a sampled signal.

DMT: Discrete multitone modulation; used in ADSL and VDSL as a line code; modulates the information on 2^x simultaneously transmitted frequencies.

DOCSIS: Data over cable service interface specification; standardized by ITU-T in 1998 for cable transmission.

Downstream: Used in the telecommunications industry to describe transmission of data from the central office to the subscriber's premises.

DSLAM: A device residing in a central office that congregates the data from multiple DSL lines and multiplexes them onto the high-speed backbone.

ETSI: European Telecommunications Standards Institute; non-profit European telecommunications standardization agency.

FEXT: Far-end crosstalk; used in the telecommunications industry to describe electrical interference signal originating from a far-end transmitter; the interference signal travels the length of the cable.

HDSL: High bit rate DSL; developed as a replacement technology for the T1/E1 transmission systems; standardized in 1998 by ITU-T G.991.1 modeled closely after the ETSI TM-03036.

ISDN: Integrated services digital network; developed in the 1980s for distances of up to 18,000ft; offers two types of services: the basic rate interface (BRI) and the primary rate interface (PRI).

ITU-T: International Telecommunication Union Standardization Sector; coordinates the work on international telecommunication standards.

NEXT: Near-end crosstalk; used in the telecommunications industry to describe electrical interference signal originating from an adjacent near-end transmitter.

POTS: Plain, old telephone service.

QAM: Quadrature amplitude modulation; modulates the information as the amplitude of two out-of-phase sinusoids.

SHDSL: Single-pair HDSL; a second generation HDSL technology reaching 18,000ft without repeaters.

T1/E1: T1 is a telecommunication signaling technique used widely in North America and Japan; E1 is used in the rest of the world;

TCM: Trellis-coded modulation; coding technique used over bandlimited channels to increase the data rate.

Upstream: Used in the telecommunications industry to describe transmission of data from the subscriber's premises to the central office.

VDSL: A very-high-speed DSL; standardized by ITU-T in 2004; it is intended to bridge short copper access line lengths (shorter than 3,000ft) at high speeds.

VoIP: Voice-over-Internet protocol; routes voice signals over an IP-based network.

xDSL: Used in telecommunications industry to describe a family of broadband access technologies.

INTRODUCTION

Long before the Internet was publicly available, computer enthusiasts were using devices that changed binary data into sounds for transmission over telephone lines. The data were “modulated” into sound at the transmission end and were “demodulated” back into data at the receiving end—modem. For many years following the advent of Internet access to the general population, the telephone modem remained the primary source of connection to the network. However, it eventually became apparent that for many of the desired uses of the network, the dial-up connection (i.e., access to the network using regular telephone modems effectively limited to less than 56k transmission speeds) was insufficient.

Internet theorists have often expressed concern over a phenomenon known as the “last mile” problem (Cairncross, 2001; Drucker, 1999) “because it represents a bottleneck that constrains the benefits the consumer gets from the rest of a network...” (National Research Council Committee on Broadband Last Mile Technology, 2002, 45). As industry and e-businesses invested in technologies to deliver a wider range of content and services over the network, there was accompanying concern over the persistence of dial-up Internet access. The most sophisticated offerings, such as streaming video services, were simply infeasible with the limitations of telephone voice-band modem connections. This last link or “last mile” of the connection between provider and consumer was therefore a major barrier in the technical and economic expansion of the Internet—particularly at the level of the retail consumer. The introduction of broadband services to the consumer market has been seen as a signal of the elimination of the last mile problem and the development of the true potential of the network (Cairncross, 2001).

To date, the two primary broadband offerings to the consumer market have been DSL (digital subscriber line) and cable modem services. The former is offered by traditional telephone companies and utilizes existing telephone lines to transmit and receive network traffic. DSL involves dedicated connections to the provider network

but is limited by distance from the provider’s closest facility. The latter is offered by traditional cable television operations and uses existing coaxial cable infrastructure (or upgraded HFC or hybrid fiber/coaxial) to carry Internet traffic. Cable broadband access involves shared connections to the provider network.

Though there are wide variations in pricing and availability of these options worldwide, in North America DSL is often cheaper, offering somewhat lower bandwidth than cable modem service. Cable modem service costs more and can be limited by the capacity of the local cable franchises, but theoretically far surpasses the speeds available to DSL subscribers.

However, numerous factors complicate the comparisons, not the least of which is the fact that cable modem speeds can drop dramatically as more users crowd the cable system. Additionally, network conditions in both forms of access can vary tremendously from one point in time to the next and providers often employ some form of “capping” or reducing bandwidth to individual customers to maintain the speed of the network.

As more and more cable systems roll out both digital cable and modem services, however, DSL continues to remain a second choice generally lagging by a two to one margin (Wilson, 2005) except where there is limited or no availability of cable modem services. DSL is especially attractive in contexts outside of North America such as South Korea (Lee, 2005) and in other places where television delivery systems may not be as firmly rooted in the community antenna television (CATV) or “cable” model. Innovations from DSL providers may, of course, change this imbalance in the future as fully fiber-optic connections and various DSL improvements are developed and tested (Reed, 2005; Wilson, 2005).

MODEMS

The Modem Concept

Claude Shannon (1948) outlined the principles of information transmission in his paper entitled “A mathematical

technologies with speeds that exceed today's fastest cable modems (Research and Markets, 2004).

CABLE MODEM ROLLOUT

Diffusion/Adoption

As with all new and emerging technologies, the early cable modem rollout has followed a predictable pattern of adoption that features particular types of consumers (e.g., opinion leaders, the technologically savvy, well-educated and wealthy) among the early adopters. Chan-Olmsted et al. (2005), for example, pointed out that cable modem technology adoption is in keeping with the established patterns of diffusion of innovations literature. These patterns predict that early adopters will usually be relatively high in socioeconomic status, media ownership and media use, innovativeness, and information seeking.

Adoption patterns and statistics have, however, demonstrated market penetration well beyond the innovators and early adopters. Crandall (2005) noted that by mid-2004, there were 32.5 million "high-speed" lines in the United States. Of this number, 30.1 million were residential and small business lines. Cable television systems provided 57% of these lines, whereas DSL provided 35%.

Cable modem technology has also evidently crossed Rogers' (1998) "critical mass" of adopters beyond which a technology will "take off" in the market. Rogers and Scott (1997) described this "critical mass" as "the point at which enough individuals have adopted an innovation that the innovation's further rate of adoption becomes self-sustaining" (Rogers and Scott, 1997). Bass (1969) proposed three factors influencing such new technology adoption: 1) "market potential" (or total number of people who will eventually use the product), 2) the likelihood of someone adopting because of external influences such as media and 3) the likelihood of someone adopting because of the influence of other adopters.

According to M2 Presswire (2005), the number of cable modem subscribers in major markets such as North America, Asia, and Europe has increased steadily over recent years resulting in growth rates as high as 35% in some markets. This widespread adoption reflects numerous individual adoption decisions taken by individual customers. The work of Everett M. Rogers (1998) and others on the diffusion of innovations has focused on the reasons why consumers are likely to adopt certain products, services, or practices. This body of knowledge tells us that a consumer's decision to adopt a new technology is likely to be influenced by five principal factors:

1. Simplicity
2. Ease of trial
3. Relative advantage
4. Observability
5. Compatibility

In the case of cable modems the issue of simplicity (or, conversely, complexity) has two main dimensions: usage and installation. Using a cable modem is often simpler than using a traditional dial-up modem. For example, the "always-on" model removes the need for dialing in

at the start of each session. Installation varies in complexity depending on the level of support from the local cable company. There is often a self-install option that allows users to save on installation fees by doing the cable modem installation themselves. This can make the installation a more complex undertaking, given that many computer systems come with dial-up modems already installed, and that software configuration is also necessary along with hardware installation. The non-technical user who opts for a service visit for the install may perceive little complexity associated with the process. However, standardization, such as is provided for by the DOCSIS standard makes the entire process easier than it would be with competing or noncompatible standards and equipment.

Ease of trial is related in some ways to the ease of installation and use cited above. Trying a cable modem service will usually involve calls to the cable company and arranging for equipment delivery or service calls. However, in most cases in United States markets, no annual contract is required. Trying cable modem service, then, is easier in some senses than either DSL or dial-up Internet access since both these alternatives tend to lean in favor of service term commitments (true for some time for DSL—only more recently a trend in dial-up whereby providers offer lower rates in exchange for a time period commitment). An often-overlooked element of the ease of trial is the extent to which consumers may "try out" high-speed Internet access through their use of high-speed connections at work or school.

In experiencing broadband access at school or work, consumers are exposed to the advantages of a cable modem compared to traditional dial-up. They may then be in a better position to evaluate the cost/benefit ratio (or relative advantage) of the move to broadband in general and the cable modem in particular with regard to factors such as usefulness, price, and convenience. Many consumers experience extremely high bandwidth and speeds on commercial/business or college-based T1 and T3 connections. This experience enables users to evaluate the DSL and cable modem services against prior high-speed experiences. This experience also gives users the ability to make more informed decisions regarding not only the relative advantage of broadband over dial-up, but also regarding the choice between DSL and cable modems with regard to price and speed differentials.

Observability refers to the question of the potential adopter being able to observe the consequences or benefits of the innovation. The difference between dial-up and cable modem access is quite clear and obvious. However, this is less the case with DSL service compared to cable modems. In such a comparison, a non-technically oriented user may not be able to observe the differences or to run relevant download comparisons or similar tests. Although the differences are clear in file downloads and other high-bandwidth processes, routine browsing and e-mail activities may not reveal observable differences.

The question of compatibility of an innovation is concerned with the extent to which the innovation is consistent with factors such as the cultural and social values, experiences, and needs of the potential adopters. It can also relate to technical compatibility and the extent to

which an adopter may have to replace or upgrade existing technologies to adopt the innovation. Cable modem adopters generally do not need to perform any significant upgrades or changes in technology and find that the new technology integrates almost seamlessly with their existing technologies.

On the service side, there are compatibility issues with legacy software and systems. Dial-up subscribers, for example, often experience some dislocation when switching to cable modem service—some even opting to maintain their dial-up accounts after cable modem adoption to preserve not only e-mail addresses but also accustomed interfaces, services, and even concepts (such as “keywords”). Traditional dial-up providers, aware of this loyalty, even provide broadband portals to their former customers or those who are migrating to broadband. These portals are little more than an interface providing comfortable and familiar screens through which the new cable modem user accesses their new broadband connection, but their old e-mails and ancillary services.

CABLE MODEM TECHNOLOGY

Speeds and Standards

Cable modems typically offer consumers speeds in excess of 1 Mbps (million bits per second). In fact, by early 2006, some major cable providers in the United States had already upgraded their systems to offer 4 Mbps downstream and 384 Kbps (kilobits per second) upstream with premium offerings of 6 Mbps downstream and 786 Kbps upstream.

Yet, these speeds would be meaningless without standards-based interconnectivity and interoperability on the networks. Networks on the scale of those developed by the cable television providers for high-speed Internet access involve numerous technical components, often from different manufacturers. Without common specifications and standards, such networks would be difficult if not impossible to create and maintain.

To promote interoperability and stability on and across networks, the cable industry (through a grouping of major industry players, affiliates and partners known as the multimedia cable network system partners or “MCNS”) introduced a set of standards in 1996 known as the “DOCSIS” or data over cable service interface specification. Laubach (2001) noted that: “The specifications were designed to be nonvendor-specific, allowing cross-manufacturer compatibility for high-speed data communications services over two-way hybrid fiber-coax (HFC) cable television systems” (Laubach, 2001, 38). The DOCSIS standard stipulated such specifics as modulation schemes and protocols for use on cable television data systems and was endorsed by major networking and computer players such as Microsoft and Cisco (DOCSIS, n.d.). According to Fellows and Jones (2001), the DOCSIS is the foundation for high-speed Internet access offered by North American cable operators. They also note that it facilitates interoperability and integration with computers as well as laying the foundation for voice, video, and data convergence along broadband lines provided by CATV systems.

Laubach (2001) identified emerging competition for broadband access in the late 1990s along with difficulties with manufacturers and a lack of development of various technical standards as the key factors prompting the move toward the eventual creation of the DOCSIS. The standard prevails today in North America and was adopted by the International Telecommunications Union in March of 1998. The DOCSIS has evolved into versions 1.1, and 2.0 with version 3.0 in development at the time of writing. The standard has also spread beyond North America and instructed development of networks in other regions (Cable Modem/DOCSIS, 2005). *Cablemodem.com* reports that three published versions of the DOCSIS specifications have been approved by major organizations such as the Society for Cable Telecommunications Engineers (SCTE), the European Telecommunications Standards Institute (ETSI), and the International Telecommunications Union (ITU)” (Cable Modems/DOCSIS, 2005).

Integration with Cable TV Networks

The DOCSIS standards have made the development of the cable-based Internet access networks easier, but they have not removed all the challenges facing cable providers who have become Internet service providers (ISPs). Significant investments in hardware and other technical improvements along with numerous technological challenges spell tremendous challenges for such operations. Among the main challenges has been the adaptation of the traditional cable network structure (a largely one-way affair) to the two-way demands of an Internet access network. Green (2002) identified the one-way nature of the conventional CATV network as a key impediment to the roll-out of new services delivered over cable, noting that the potential for increased revenue has led most operators to develop two-way capabilities and that some franchising authorities have compelled operators to develop such capabilities.

Bates (2002) noted that: “CATV has always been considered a one-way transmission system, designed to deliver TV and packaged entertainment to the residential marketplace” (Bates, 2002, 221). He suggested, further, that there was little impetus before the advent of the cable modem for any other form of network, because the coaxial cable infrastructure was traditionally sufficient to provide an acceptably large number of channels to the local subscriber. The situation of local monopoly and a generally fixed channel lineup (i.e., predictable bandwidth requirements) also meant that there was no impetus to challenge the capacity of the network or its fundamental operating principles.

Both competition from direct broadcast satellite (DBS) services and the demands of Internet access have spelled major challenges and changes for the traditional cable television networks. Somewhat ironically, it is this provision of broadband Internet access and related VOIP (voice over Internet protocol) service that now serve as a major selling point for cable providers in their battles against the dishes. This followed the commercial failure of early dish-based broadband services featuring one way downstream service from the satellite provider and upstream service via a telephone line in what is known as

a TRI (telephony return interface) system. The one-way nature of the traditional cable television networks and the new bandwidth demands, however, have been major hurdles in the transition to Internet access.

Network Components and Structure

CATV systems were traditionally only able to manage small amounts of two-way data flow intended to facilitate such things as pay-per-view purchases. Bates (1999) noted that these systems “have historically carried a number of data services. These services have ranged from news and weather feeds, presented in alphanumeric form on single channels or as scrolling captions, to one-way transmission of data” (Bates 1999). The two-way nature of Internet access, however, has placed much higher demands on the CATV systems, requiring fundamental re-engineering and the addition of significant new components. The most important added component in an Internet-access/cable television network is the cable modem termination system (CMTS).

The CMTS provides the primary interface with the Internet, feeding data signals downstream into the headend transmitter (Figure 2). In such a system, the headend transmitter combines these data signals with the audio and video feeds from the cable provider and transmits the combined information to subscribers along a coaxial, fiber, optic, or (most commonly today) hybrid network. Similar to the cable system’s ability to reference individual subscribers by unique addresses on their addressable cable boxes, the CMTS is able to communicate with individual cable modems on the network via their MAC addresses, and is therefore able to route data requests from individual modems to the Internet and deliver responses individually.

In cable data systems the CMTS is managed by an element management system (EMS) that administers day-to-day tasks. According to the IEC (2005), the operations tasks associated with the EMS include “provisioning, day-to-day administration, monitoring, alarms, and testing of various components of a CMTS” (online at http://www.iec.org/online/tutorials/cable_mod/topic01.html).

As the network structure becomes larger and more complex, added clients may be located farther and farther away from the headend and other key components.

In such cases attenuation becomes an issue with modems further from the headend facing longer hops for each packet sent upstream or downstream and greater potential for numerous types of interference along the way. Certain components of the network layers are designed to deal with this structural issue.

Network Layers

As in other computerized networks, data transmission and management as well as other functions in a cable modem network are arranged in a number of layers. The *physical layer* incorporates a downstream and an upstream data channel and translates data to and from digital form for use by upper layers of the network. Downstream data is transmitted as MPEG-2 frames in what is known as the “*transmission convergence layer*” or “*downstream convergence layer*” within the physical layer (Cisco Systems Inc, 2002). A MAC layer facilitates sharing of the upstream data channel by many modems and makes adjustments for variations in the distances of particular modems from the head end. The *network layer* uses Internet protocol (IP) with dynamic host configuration protocol (DHCP) that automates the assignment of IP addresses to clients on the network. These networks also feature a *transport layer* using transmission control protocol (TCP) and user datagram protocol (UDP), whereas an application layer supports various Internet program functions (IEC, 2005). Another important component of the network is the baseline privacy interface (BPI) data link encryption system that encrypts information between individual modems and the CMTS for user privacy.

Security

Within a given cable system, the cable modems in subscribers’ homes are all connected to a single network. This shared architecture raises questions about the security of data and the privacy of individual connections. Truelove (2003), for example, warned of “inherent security risks” with cable modem broadband Internet access, pointing that communications among domestic local network elements such as PCs and printers are available to others on the network, whereas TCP/IP packets between the user’s PC and the Internet may be particularly vulnerable to interception along shared segments on the network. However, Laubach (2001) noted that despite these vulnerabilities, cable modem systems if “properly administered” can be quite secure. The security of individual connections on the network is ensured by measures such as encryption of data between the CMTS and the subscriber’s cable modem. Basic security precautions involving such encryption and the security of individual connections are provided within the DOCSIS standards.

Like so many other aspects of computer networking, these safeguards are rarely sufficient on their own and inadequate in the face of active interference. Among the threats to the cable modem network are actions by subscribers to subvert network regulations or protections. For example, Poulsen (2004) exposed the plans of a group of hackers to simplify a range of assaults on cable modem networks that would “topple long-held assumptions

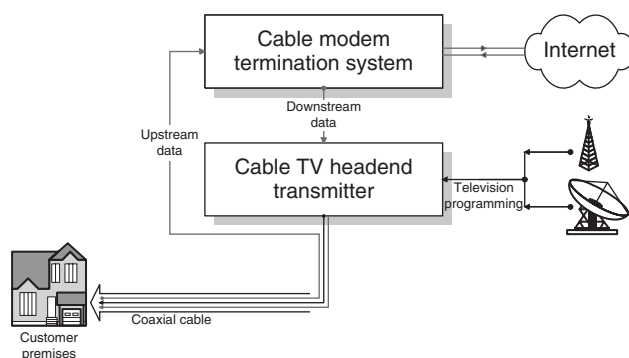

Figure 2: Cable modem integration into CATV system

about the privacy of cable modem communications.” This involved a downloadable program called Sigma that would automate processes involved in overriding network imposed limitations and security precautions, giving users “almost complete control of their cable modem—a privilege previously reserved for the service provider” Poulsen (2004) suggested that such actions violate service agreements and even the law when users change modem configuration files to uncap service limitations or even receive free service by running unregistered modems. Under the DOCSIS specifications, users are not allowed to adjust the configuration files even on modems that they own as this is a function reserved for the provider in order to control such things as bandwidth allocation.

Vulnerability within the network is one concern. Protection from outside attacks is another. Cable system-based Internet access providers face challenges similar to those faced by other networks and ISPs. Their security measures may include many of the same approaches as other major networks including firewalls, proxy servers, and the use of secure socket layer (SSL) connections for data collection functions.

However, there is another dimension of security concerns at the consumer end of the connection. The cable modem subscriber is faced with a connection to the Internet that is “always on.” Whereas with a dial-up connection, the user made an active decision to log on to the Internet, with a cable modem connection the user is logged on every time their computer starts up. This leads to at least the perception (and, to some extent the reality) of greater risk. Laubach (2001), for example, suggested that the always-on connection is more susceptible to attacks. When this perception is coupled with the notion that a faster connection leads to more diverse online activities and downloads that may be almost instantaneous, the user is likely to perceive much greater risk from the broadband Internet connection than a dial-up connection. These dangers include the risks of infection by viruses and spyware, and the possibility of identity theft or falling victim to online scams and frauds. Some companies even trade on these fears, encouraging the idea that risks increase with broadband connections. An America Online press release (2005), for example, quoted a named company official as saying:

A broadband connection is basically an open pipe to the Internet, which means that high speed users are particularly vulnerable to thousands of new viruses and spyware threats as they emerge.

Although it is certainly possible to argue that many of these same risks are equally true when applied to dial-up scenarios, it is easy to understand why the user who has embarked upon more diverse Web surfing activities made possible by a cable modem connection (Rappoport, Kridel & Taylor, 2003) might be concerned. The level of risk, of course, may have more to do with the surfing habits of the user than the speed of the connection, but certain risks are undoubtedly exacerbated by higher speed and greater bandwidth. Among the real concerns here are programs and pseudo-programs in the form of trojans,

viruses, or spyware that may transmit personal data from the user’s computer to be collected by unknown or nefarious elements for various purposes ranging from tracking surfing habits to (conceivably) perpetrating identity theft. The high speed of broadband connections may also mask the outward transfer of data in this case as any decline in speed due to that transfer becomes less perceptible.

Cathey and Wiggins (2002) argued that the persistent IP (Internet protocol) address associated with cable modems also increase risk. They point out that dial-up users are assigned different IP addresses at each login, but that broadband users who typically leave their cable modem or other appliance on all the time face risks associated with not periodically changing their IP address—particularly if an attacker identifies a persistent IP address and sets up a packet sniffer targeting the address. These persistent IP addresses allow a potential intruder multiple opportunities to attack a single target. Such risks, however, are not necessarily inherent in the system and pose little additional threat since an attacker could just as easily target a range of IP addresses issued by an ISP—whether dial-up or cable—accessing the packets of the random users who match the targeted addresses. The specific case of an attacker targeting a known IP address would probably involve more than just random hacking and intrusion. Cable modem providers and other industry players have been actively pursuing measures including IP randomization to correct for this weakness.

LEGAL AND BUSINESS ISSUES

The diversification of the cable television provider into a provider of Internet access and other services such as telephony has raised a number of legal issues—particularly surrounding the identity of these companies. Among the concerns in the United States is the question of whether these former cable providers can now be categorized as either ISPs or telephone companies or both. There are implications here not only for taxes and public policy, but also for competition in the marketplace.

Rulings have centered on issues such as the definition of cable modem Internet access as an “information service” but not a “cable service”—the latter being subject to certain fees that do not apply to the former (Tantono, Porcelli, Bagner, and Sonu 2002; Leanza, 2004) as well as issues of open access to cable infrastructure by competitors. Related to these questions is the debate over what is termed *asymmetric regulation* (Hausman, 2003)—with particular regard to whether cable providers of Internet access should be subject to the same rules of access and inter-accessibility as operators of more traditional public networks such as the terrestrial conventional telephone system. The argument for such similar regulation is based in part on the perception that the cable modem providers provides similar services as and even usurp the business of the traditional telcos.

VOIP

Consider for example, the former cable television provider that develops both Internet access and telephony

offerings. The cable system provides telephone service via the Internet using what is known as voice over Internet protocol (VOIP). More recent cable modem models feature a built-in telephone port to enable the customer to plug a conventional telephone appliance directly into the modem for VOIP service. When a VOIP customer calls another VOIP customer, the call is routed entirely along the Internet, though at the user end the process is completely transparent and for all intents and purposes it is simply a telephone call. No computer is directly involved in the user experience. If the VOIP customer calls a traditional telephone, the call is routed along the Internet up to the closest local exchange of the destination telephone. All of this results in much lower calling costs with reductions even on international calls.

One of the problems with this scenario is that the cable company is not subject to the same regulations as the telephone companies. To complicate matters further, the cable based VOIP providers are also in direct competition with the telephone companies on another front, that of Internet access. The provision of VOIP service with Internet access all via a cable modem not only removes the need for a telephone line from the traditional telephone company, but also effectively removes the possibility of DSL services from a traditional telephone company.

A further issue with regard to VOIP provision over cable modem networks is that of emergency or 911 calling. The Federal Communications Commission (FCC)/National Association of Regulatory Utility Commissioners (NARUC) Joint Task Force on VoIP/E911 (2006) has noted in an FCC consumer advisory what it called a "critical public safety gap" associated with VOIP services. Factors such as the subscriber's ability to use a VOIP device from any broadband connection contribute to difficulties in locating callers in emergency situations. The FCC has therefore required interconnected VOIP services (that use the public switched telephone network to route portions of their calls) to take certain measures to protect consumers. These measures include mandatory provision of 911 service, obtaining the customer's residential address before activation, and obtaining acknowledgments from customers stating that they are aware of the limitations of 911 services provided via VOIP.

Cable Modems and File Sharing

For many users, the cable modem makes the practice of file sharing possible. File sharing is a valid and important technology that stands to enable researchers, scientists, and others to make important files available to others. The controversy over file sharing has to do with what music and film industry interests characterize as illegal exchanges of copyright material. Ongoing legal disputes have included huge multinational corporations suing private individuals over the practice of sharing music and video files. For most, file sharing is difficult and impractical, if not impossible, without a broadband connection. The increasing reach of broadband has also send further developments in file sharing technologies such as the emergence of torrent style sharing that marks a technological advance over traditional peer-to-peer sharing.

Commercial File Delivery

New products and services have become available or feasible because broadband access (led by the popularity and speed of cable modems). Chief among these is the slew of "legal" or commercially endorsed music purchase systems. These range from streaming audio services to downloadable music. Even more dependent on the speed and bandwidth of the cable modem is the provision of streaming and downloadable video on the World Wide Web. Software producers also take advantage of the availability of the high speed and bandwidth by providing their products for direct download. Customers at many commercial software sites can now download not just updates and fixes but also full versions of software after paying the appropriate fees. Cairncross (2001) would describe these transactions as representing trade in what she identified as completely "digital products," because they never need to occupy a physical form like traditional products.

E-commerce Developments

Other benefits to e-commerce beyond file delivery include the possibility of delivering more complex and detailed product descriptions and interfaces to customers across the Web. These include multimedia animations and even interactive three dimensional displays of products that were hitherto impractical without broadband. Less obvious elements of e-commerce are also aided by the cable modem, including the commercial provision of distance education and the feasibility of more sophisticated financial services online. Limitations remain, however, on the spread of these benefits into the international market despite the global reach of the Internet. Among these limitations are traditional barriers such as language differences and emerging barriers such as the discrepancy in the spread of broadband technologies in many countries.

Telecommuting

The cable modem with its high-speed capabilities, reliable connections and wide availability creates greater potential for telecommuting. Although the benefits and costs of telecommuting are still hotly debated, the possibilities of richer connections that are more readily available generally enhance the chances for successful telecommuting arrangements. Laughbach (2001, 256) notes, however, that this same broadband advantage also "increases the vulnerability of home computing equipment and, subsequently, threat to electronic commerce and telecommuting in the United States."

Telecommuting (or telework) and its variants have seen strong levels of adoption boosted by the power of broadband connections to facilitate such services as video-conferencing. However, barriers to adoption remain in place despite fast connections. Among these are reluctance from management to provide the facility, concerns about security and employee concerns about being marginalized or otherwise displaced from the workplace (U.S. Office of Personnel Management, 2003).

CONCLUSION

The advent and diffusion of cable modem technology at both the consumer and provider levels has marked a quantum leap into the world of broadband access for many in the United States and, increasingly, in other regions and countries. The successful deployment of this group of technologies has come as a result of astute technical planning (including negotiations with manufacturers and alliances among industry players). It has also benefited from the fortuitous pre-existence of successful and widely diffused cable television technology. Consumer familiarity with the concept of cable connections and the relative ease of connection and use of cable modem technology have aided the diffusion of the technologies, as has the increasingly widespread availability of broadband access of various types at businesses and educational institutions.

The transformation to cable modem Internet access has meant significant investments and technical improvements for cable providers and the emergence of associated services such as VOIP has raised serious regulatory and business-related issues. However, the lower costs and integration of services (e.g., cable television, Internet access, and voice) are proving attractive to the consumer market.

Consumers have benefited from competition between cable modem and DSL providers that keep prices low and raise the stakes for provision of higher speeds. The strengths and weaknesses of each type of broadband connection provide different benefits and risks to the consumer in terms of speeds and security. This situation is likely to continue in the short to medium term, spurring both technical development and further diffusion of broadband.

The long run prospects for cable modem technology appear to be quite positive—particularly in light of the robust networks that exist, the investments in infrastructure being made by the industry, the development and continual improvement of widely accepted standards, and the provision of cost-effective and feasible services. Legal disputes and regulatory questions notwithstanding, the technology is placed to spread even more widely and even to further diversify its consumer offerings in the medium to long term.

GLOSSARY

Bandwidth: A measure of the capacity of a transmission medium to carry data in terms of the number of wave frequencies transmitted. High bandwidth is associated with high rates and capacities for data flow.

Broadband: Describes electronic data exchanges or channels that allow for fast transmission of large amounts of data. Particularly common in distinguishing higher bandwidth systems from dial-up modem connections of the past.

Cable Modem: A device that allows digital signals to be transmitted and received through radio frequency (RF) modulation and demodulation on a coaxial CATV system.

CATV: Community antenna television—original and technical terminology for cable television systems.

CMTS: Cable modem termination system—a system to which all *cable modems* in a CATV-based Internet

access system are connected. The CMTS interfaces between the modems and the Internet and routes data to and from specific modems on the system.

DOCSIS: Data over cable service interface specification—a set of standards established through industry consultation providing rules, procedures, and specifications to ensure equipment and systems conformance and interoperability for the delivery of Internet access over coaxial cable television networks.

DSL: Digital subscriber line—a system of modulation over the conventional telephone network utilizing specialized modems to provide broadband access.

EMS: Element management system—a network management and operations system used to control one or more *CMTS* and associated subscriber connections.

Encryption: The process of coding messages into forms that obscure their meanings—usually until such messages are received by an intended recipient capable of decoding the meaning—often by use of some type of decoding instrument or “key.” Used in computer data transmission to protect data from interception by unintended parties.

Internet: A global network of interconnected network of computer networks using a common system of rules for data exchange.

IP address: Internet protocol address—a number assigned to a particular Internet connection or device to enable routing of messages on an appropriate network.

ISP: Internet service provider—any of a number of different types of services that enable users to connect their computers to the Internet.

Modem: Modulator demodulator—a device that encodes messages into a particular sequence for transmission over a communications channel, and decodes similarly encoded sequences that are received.

Spyware: Any of a range of different types of software that enable the (usually unauthorized) transmission of data from a user’s computer and/or track various user activities such as browsing histories, passwords, and user IDs. The general term “malware” has come to encompass various types of spyware, as well as Trojans (programs that infiltrate users’ computers without their knowledge) and viruses (programs that intentionally wreak harmful or destructive effects on users’ computers).

SSL: Secure socket layer—a system of secure connections commonly used in e-commerce and other high-security transactions over computer networks.

VOIP: Voice over Internet protocol—a system for delivery of telephony services over computer networks.

INTRODUCTION

Home networks facilitate communication among appliances, home systems, entertainment products, and information devices in a home so that they can work cooperatively and share information. A device connected to a home network gains the capabilities of other networked devices, and as a result the device can provide a service or function that it would have otherwise been incapable of providing alone (Rose 2001). Several factors are pushing for the wide development and adoption of home networks. These include the advancement in telecommunications technologies, the wide proliferation of personal computers, and the decreasing costs of smart devices that allow users to control and monitor events in consumer-based appliances, and consumer demand for content-rich applications.

In the last few years, we have experienced a growing interest to advance state-of-the-art technologies to ease the adoption and deployment of home networks. In recent years, networks are being increasingly used in home environments. Information appliances such as digital TVs, videocassette recorders (VCR), set-top-boxes, personal computers (PCs), and mobile devices, such as personal digital assistants (PDAs) and cellular phones, can all be connected. Many of these appliances can be classified into two broad categories namely, those with high computational resources and capabilities (including processing power, memory, disk space) and those devices (PDAs, cellular phones) with little computing power.

The home networking industry is currently made up of various companies, organizations, vendors including

Internet service providers, networking vendors, international standardization bodies, PC manufacturers, semiconductor manufacturers, home appliance developers, telecommunication providers, consumer electronics vendors, and middleware (including software) vendors. All of them are fueling the growth of home control and automation products have grown to 9.2 billion worldwide in 2006 (compared to 1.4 billion in 2001) (Cahners In-Stat Group 1999). Driven by compelling applications, decreasing hardware/software prices, and easier configurations, home networking is expected to penetrate 27 percent of U.S. households by 2008 (Greenspan 2003). As shown in Table 1, a recent report (IDC 2004) forecasts that worldwide households with home networks are expected to grow by 25 percent by the year 2008.

Most home networks deployed recently are typically made up of one or all of the following subnetworks (as shown in Figure 1) including:

- A *computing network*: this connects mainly the various PCs in the home to share files, printers, and broadband connections. This network also carries multimedia data such as audio, video, and images for applications such as video conferencing and voice over IP (VoIP). File transfer traffic, interactive traffic (generated by applications such as Telnet and secure shell) as well as Web traffic (browsing data) are also delivered through the network.
- A *home automation network*: this connects devices such as lamps, heaters, security devices responsible for home users comfort and security. Security traffic, originating from home network devices such as security camera,

Table 1: Forecast of home networks adoption by United States and worldwide households (Shaw 2004)

	2004 (millions)	2008 (millions)	Projected Increase (%)
Worldwide households with home networks	89	111	25
US households with home networks	13.5	36.6	171
US households with wireless access points, gateways, routers	10.1	35.1	247

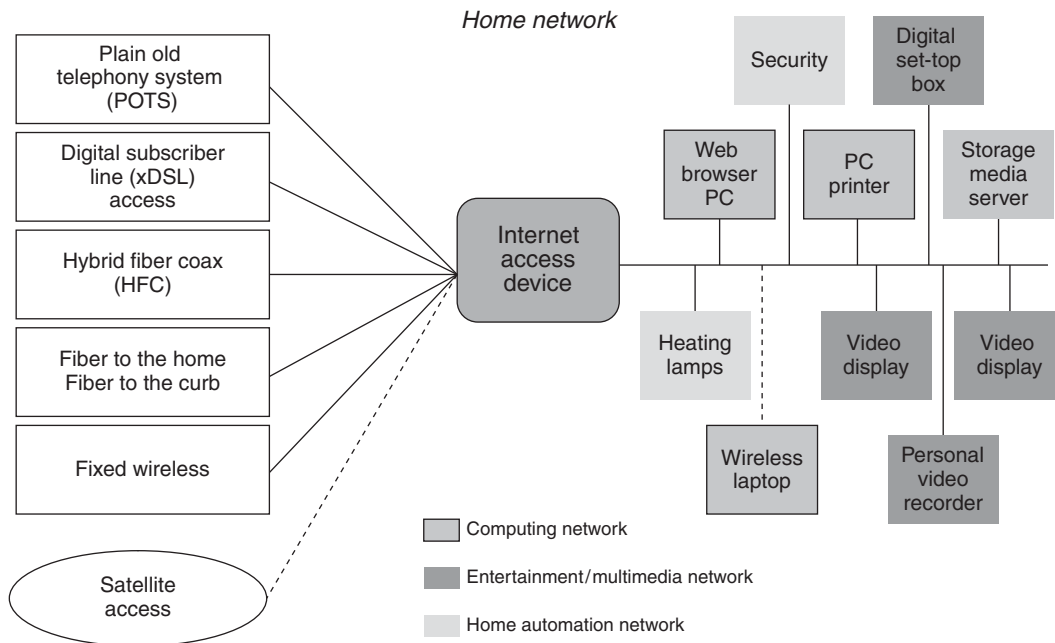

Figure 1: Remote Internet access to heterogeneous home network devices

and home device control traffic consisting of mainly control signals used by home devices are generated by the home automation network.

- An *entertainment network*: this connects devices such as digital set-top-boxes to personal video recorders¹ (such as TiVo or Replay TV) to stream video using standard-based Internet protocols and are often part of some system connected to a cable or satellite provider.

FACTORS INFLUENCING THE GROWTH OF HOME NETWORKS

Market for home networking and devices connected to home networks will grow from \$14 billion in 2005 to more than \$85 billion by 2011 according to recent ABI forecasts (ABI 2006). Various factors have been contributing to the dramatic growth and adoption of home networks. These home networking market drivers include:

- *Multiple PCs per household*: the decreasing costs of hardware/software and Internet access are enabling home users to acquire multiple PCs.
- *High-speed broadband Internet access*: in the last few years, many last mile high bandwidth Internet access solutions such as cable and digital subscriber lines (DSL) have been accessible to home users at low costs. Many of the broadband access technologies provide high-speed Internet data transfers with “always-on” connectivity. Consequently, many Internet applications such as video streaming, new streaming, games can now be supported with little impact on their quality (in contrast to past Internet connections based on dial-up access lines which significantly reduce connection performance).

¹A consumer video device that allows users to capture television programming to internal hard disk storage for later viewing.

- *Decreasing costs of communication devices and peripherals*: the cost of many networking devices such as hubs and switches along with peripherals such as cameras, scanners, and printers have been declining very rapidly in recent years making them more affordable to home users.
- *Widespread use of handheld devices and other smart devices*: many handheld devices have emerged recently ranging from personal digital assistants to cell phones most of which are often equipped with full Internet access enabling anytime, anywhere connectivity. Handheld users often need to communicate with other devices in the home environment for tasks such as backup, storage, and Internet connectivity. These tasks can be achieved transparently with a home network.
- *Impact of telecommuting*: we have witnessed a growing number of employees who are opting to work from home whenever possible. In fact, IDC Corporation predicts that there will be an estimated 9.9 million telecommuters in the United States by 2009. This has led to an increase in the number of small office home offices (SOHOs). To enable the convenience of office users, home networks are being deployed to provide access to computing and network resources to telecommuters (IDC 2006).
- *Emergence of Internet appliances*: many Internet appliances (typically used to describe non-PC devices that allow access to Internet content) have emerged on the market in recent years. Common examples include the Honeywell WebPAD, Microsoft's WebTV, Netpliance's I-Opener, Compaq's iPaq Home Internet Appliance, or the Sony PlayStation 2. These appliances are being connected to the Internet. Their ubiquity, deployment, and management in homes are being enabled by home networks (Das and Cook 2004; Zhaohui et al. 2004; Eckel et al. 2003).

- **Home automation:** from a consumer perspective, a home network facilitates communication among appliances, home systems, entertainment products, and information devices in a home, and enables them to work cooperatively and share information. This allows users to get information about the home condition and to remotely control home systems and appliances, as well as to gain access to information and entertainment resources from inside and outside the home. Home automation services including security, lighting, and heating are driving the need for home networking. It is also worthwhile pointing out that the capability to provide various monitoring services in the area of remote healthcare (through various sensing and monitoring devices) to elderly, sick or disabled people are also motivating the need for the deployment of home networks.
- **Consumer demand:** the demand for rich content and content-rich applications spawned the development of “convergence” products that combine the features of several consumer electronics products into a single device. Home networks have evolved into a “distributed convergence” model that is based on sharing content and functions among devices in the home. A device connected to a home network gains the capabilities of the other networked devices. Thus a networked device can provide a service or function that it is incapable of providing alone. Therefore, the home network provides the communications structure that allows the individual devices to operate as a larger cohesive unit (Marples and Moyer 2004).
- **Online gaming:** network (on local area networks) or Internet (across the Internet) gaming applications are increasingly being deployed in home networking environments. This trend continues to generate more money every year. For example, the Xbox 360 video gaming system, developed by Microsoft, is more than a just a new generation game console but is expected to become a centerpiece of future networked homes that provides both traditional and non-traditional gamers powerful gaming platforms in the comfort of their homes. Xbox’s Ethernet connectivity support as well as wireless capabilities makes it well suited for home deployments at low costs. The portable gaming market is also experiencing significant competitions with the emergence of handheld game devices such as the Nintendo Dual-Screen (DS) and most recently the Sony Playstation Portable (PSP) with much larger wide-screen displays and more powerful capabilities. All these developments in the gaming industry are becoming important drivers of home networking.

Cahners In-Stat Group (1999) reported on the main reasons that motivate home users (as consumers) of home networking products to deploy home networks. Some of most salient benefits encouraging home users to adopt home networks include:

- **Shared Internet access:** home networks, in conjunction with devices called media gateways, allow different members of a family to simultaneously use a single, fast Internet access, thus saving money by having only one Internet Service Provider (ISP) account.
- **Leverage existing investments:** home users want to leverage current investments in devices and appliances such as computers, set-top boxes, personal video recorders, digital cameras, and cable modems. Home networking technologies and networks enable the sharing of various hardware resources. For instance peripherals such as printers and scanners can be accessed by multiple computers reducing costs.
- **File sharing:** users can easily share files, graphics, digital photographs, and other resources quickly through a home network compared to the use of other media such as disks, compact discs, etc. Exchange and distribution of large documents and media files such as video, MP3, and other digital content between information appliances can also be achieved more efficiently with home networking support.
- **Evolving services:** home users want to have anywhere, anytime, in-home access to services such as voice over IP (VoIP), videophone, videoconferencing, remote monitoring, and multiplayer gaming, which can all be supported by an underlying home networking infrastructure.

HOME NETWORKING TECHNOLOGIES

As we mentioned previously, home networking has been receiving a lot of attention recently by home users, service providers, and consumer electronics manufacturers. Home networking initially started out as a way to connect multiple PCs in the home and having them simultaneously share a single Internet connection. This home networking trend has changed dramatically in the last few years with the emergence of the various applications and services (such as gaming, home control, distributed video, monitoring/security, and so on). Most of the efforts undertaken in the area of home networking by numerous consortia, standardization organizations, consumer electronics manufacturers, designers, developers, and researchers are being directed to three main areas:

- **Connection technologies:** various competing technologies have been developed to help solve the issue of physical connection among home network devices. Many of the networking technologies (wired and wireless) now provide cost-effective ways to deploy a seamless network infrastructure in the home.
- **Middleware technologies:** home networking has expanded to include a wide range of network-enabled products including digital audio/video servers, VoIP systems, Internet appliances, and many others. These new products add value and functionality to home networks but at the same time they have also made the management of home networks more complicated for consumers. The high heterogeneity of devices connected to the home network is pushing researchers and designers to explore middleware technologies that can be deployed to address the interoperability issue.
- **Remote Internet access to home networks:** the traditional approach to home automation focused primarily on intuitive interfaces to simplify the management

and operation of networked homes. As a result, most home networking solutions have been exploiting wall-mounted keypads or tabletop touch panels through which a home user can synchronize, modify, and adjust setting for lighting, security, heating devices, and others. However, these interfaces only help users control their home devices while they are at home. The ubiquity of Internet access which enables anytime, anywhere access of information is also causing a shift in the way consumers want to access their home networks. The key is the provision of remote access to home networks. In a recent study by the Consumer Electronics Association on "Consumer Expectations of the Networked Home," almost 33 percent of consumers would want to exploit Internet access to monitor their homes, and 36 percent would want email notifications at work about events (delivery of a parcel, children arriving home, and so on) happening at home.

Connection Technologies

The various types of connection technologies that can be used in home networking environments can be classified according to the whether or not a new wiring of the home is needed to install the home network infrastructure. In addition, wired connection technologies can be distinguished from wireless ones. We present below a brief overview of some of the most popular wired and wireless technologies.

Various networking connection technologies are competing for the home market. These technologies can be broadly classified into three main categories: no new wiring, those technologies that require new wiring to be installed in the home, and connection technologies that are wireless (no wires).

No New Wiring

Phonelines. In 1998 the computer and semiconductor industries created the Home Phoneline Networking Alliance (HomePNA) (HomePNA 2006a) to select, promote, and standardize technologies for home phone line networking.

HomePNA initially introduced a first-generation (HomePNA 1.0) 1-Mbps technology (based on a system developed by Tut Systems Technology) followed by a second-generation (HomePNA 2.0) 10-Mbps technology (HomePNA 1999). Although HomePNA 2.0 quality of service-enabled (QoS-enabled) equipment manufacturers do provide priority support for voice traffic, HomePNA 2.0 was inadequate in its QoS support for high bandwidth audio/video streams. In 2003, HomePNA announced its third-generation (HomePNA 3.0) phone line technology that can support data rates up to 128 Mbps and, with optional extensions, data rates up to 240 Mbps. This third-generation technology addressed the QoS support inadequacy by having in-built, deterministic QoS support. HomePNA 3.0 can be used to meet the bandwidth requirements of emerging home multimedia networks that often need to deliver multiple, high-bandwidth digital audio and video streams simultaneously. HomePNA 3.0 has QoS support that allows it to deliver multimedia streams with QoS guarantees in the presence of on going best effort traffic. HomePNA technology uses 802.3 Ethernet framing and carrier sense multiple access with collision detection mechanism.

Phone line networking exploits existing phone lines wiring (no new wires need installation) in the home, is cheap and easy to maintain. Networking over the same phone line infrastructure suffers from several impairments such as high attenuation, reflections, impulse noise, and cross-talk. These issues need to be resolved in the future (HomePNA 2006b).

Powerlines. Powerline systems use electrical power lines to deliver high-speed voice and data services. Powerline carriers operate by transmitting high frequency data signals through the same powerline wired network used to deliver electrical power to homes. Devices outside the home (known as "outdoor devices") and devices inside the home (known as adapters) are used to handle the voice and data signals in the local transformers and filter the signals out to feed them into various home appliances respectively.

The principal benefit that is attributed to powerline systems is the wide availability of the wired infrastructure that is already in place. As a result there is no need for new wiring, and such systems are cheap and easy to maintain. However, powerline systems have several disadvantages: they can potentially cause interferences with other home devices and appliances such as radio, television, and telephones, they cannot bypass transformers, the maximum access speed of powerline systems is limited by the number of users simultaneous sharing the system (typical data rates offered by several powerline technologies range from 500 Kbits/s to 10 Mbps), no QoS support, and high voltages (hundreds of volts) need to be handled (Lonestar broadband 2006).

It is worthwhile stressing that despite these disadvantages, the most serious drawback of powerline technologies are their use of proprietary protocols which makes interoperability very difficult ultimately impeding its acceptance by the home networking market. To address the proprietary issue the HomePlug Powerline Alliance (a non-profit industry association) (HomePlug 2006) was set up to promote an open specification for home networking products and services to leverage the worldwide pervasiveness of residential power lines. The HomePlug specification promises several benefits (cost-competitive, high-speed connectivity at Ethernet data rates) for home networks and the success of this standard will be known only in the future.

New Wires

The low cost of Ethernet makes it a popular local area network technology that is being widely deployed in home networks using either coaxial cable or twisted pair (connected to a hub to connect multiple computers). In recent years, new wiring technologies such as the universal serial bus (USB) (USB 2006) and the IEEE 1394 Firewire (IEEE 1394 2006) standards have also become available on the market. USB is widely covered in the literature already. In this work, we focus on IEEE 1394. These technologies can be used also to support a home networking infrastructure.

IEEE 1394. The IEEE 1394 (also known as the Firewire standard) is an international standard, low-cost digital

interface developed by the IEEE 1394 working group, IEEE 1394. The Firewire interconnect technology was designed to connect computers and peripheral devices. Home networks can be designed using Firewire hardware/software technologies which support data rates up to 400 Mbps making it suitable for high-speed data and multimedia transfers. IEEE 1394 allows up to a maximum of 64 devices that can be connected on a single bus and up to 1024 individual buses can be connected.

Several design features of Firewire such as single-wire cabling for all devices, low cost, hot pluggable capability (allowing users to add or remove devices from the network without affecting the operation of other connected devices), flexible peer-to-peer topology (support of daisy chaining and branching for true peer-to-peer communication), ease of use (no need for terminators or complicated setup), non-proprietary, and its support for both asynchronous (the traditional computer memory-mapped load and store interface where data requests are sent to a specific address and an acknowledgment is returned) and isochronous (providing guaranteed data at a predefined rate, which is particularly important for multimedia transfers) data transfers.

Wireless Technologies

For some home users, large-scale rewiring of their homes is not affordable. For others, the installation of new wires in their home environments can be a cumbersome process. For both of these cases, the deployment of home networks becomes difficult. Competing technologies such as those based on wireless networking technologies can solve these issues (i.e., rewiring or new wires) and represent the “no-wires” solution (Zahariadis and Salkintzis 2003). In addition, wireless solutions also enable user mobility. Popular wireless networking technologies that have gained great popularity in home networks recently include wireless local area networks based 802.11 standards, Bluetooth, and HomeRF. Figure 2 shows a comparison of the adoption of wireless-based home networks compared to wired-based home networks in the last few years and estimated growth in the next few years.

A more in-depth review is given by Vaxevanakis et al. (2003).

Figure 2: Growth of wired-based home networks compared with wireless-based home networks (Greenspan 2003)

Wireless Local Area Networks. The IEEE 802.11 project has set up several universal standards (IEEE Standard 802.11-1997, 1997), (IEEE Standard 802.11a-1999, 1999), (IEEE Standard 802.11b-1999, 1999) for wireless local area networks (WLANs) operating in the 2.4 GHz and 5 GHz bands. Table 2 gives a brief overview of the evolution of IEEE 802.11 standards in terms of frequency range, air access scheme, data rate, and compatibility with other technologies. In addition to these standards, we also include a European standard called higher performance radio LAN2 (HiperLAN2) (Ghazi-Moghadam 2001). HiperLAN2 was developed under the European Telecommunications Standardization Institute (ETSI) Broadband Radio Access Network (BRAN) project (Kruys 2006). HiperLAN2 is similar to IEEE 802.11a in that both use the 5-GHz band and OFDM. The 802.11 Study Group addresses the interoperability between 802.11a and HiperLAN. Wireless home networks can exploit any of the wireless communication technologies given in Table 2 depending on their bandwidth requirements.

Bluetooth. Bluetooth (Bluetooth 2002; Bisdikian 2001) enables the creation of ad-hoc networks based on the concept of master/slave devices and provides full-duplex transmissions using a slotted time division duplex (TDD) scheme. Master to slave transmissions always start in an even-numbered slot whereas slave to master transmission starts in an odd-numbered time slot. The master controls data transmission of up to 7 slaves using a polling mechanism. Slaves cannot communicate with each other in Bluetooth. Transmission is only between a slave and a master or vice versa. Slaves are allowed to transmit only after being polled. The device that initiates the connection is defined as the master. Three configurations are supported by Bluetooth: point-to-point connection, point-to-multipoint (known as a *piconet*), and multiple interconnected piconets with overlapping areas forming a *scatternet*. A Bluetooth unit can simultaneously be a slave of multiple piconets, but a master in only one, and can transmit and receive data in one piconet at a time. This implies that time division multiplexing is needed for participation in multiple piconets (Haarsten 1999). All these characteristics make Bluetooth a strong candidate for personal area networks which can be deployed within home networks.

HomeRF. The HomeRF Working Group (HRFWG) (HomeRF 2006) was formed to provide the foundation for a broad range of interoperable consumer devices by defining an open industry specification for wireless digital communication between PCs and consumer electronic devices anywhere in and around the home. The HomeRF group has developed a technology called the shared wireless access protocol (SWAP). Relying on FHSS technology, SWAP includes support for both carrier sense multiple access with collision avoidance (CSMA/CA) and time division multiple access (TDMA) to deliver data and voice services respectively. First-generation HomeRF products operate in the 2.4 GHz unlicensed bandwidth (the same band 802.11 and Bluetooth both use) to deliver services among PCs, cordless telephone handsets, and other consumer electronics products at a throughput of 1.6 Mbps. It is designed to operate throughout a

Table 2: IEEE 802.11 standards and HiperLAN2

	Frequency Range	Air Access Scheme	Data Rate (Mbps)	Compatibility
802.11	2.4 GHz	FHSS, DSSS, Ir	1 and 2	N/A
802.11b	2.4 to 2.4835 GHz	DSSS using CCK	Up to 11	Compatible with 802.11 DSSS 1 and 2 Mbps
802.11a	5.15 to 5.25 GHz (50 mW), 5.25 to 5.35 GHz (250 mW), 5.725 to 5.825 GHz (1 W)	OFDM	Up to 54	Not compatible with 802.11 and 802.11b
802.11g	2.4 to 2.4835 GHz	Mandatory CCK and OFDM, Optional PBCC and CCK/OFDM	Up to 54	Compatible with 802.11b; not compatible with 802.11 FHSS, Ir
HiperLAN2	5.15 to 5.35 GHz, 5.470 to 5.725 GHz	OFDM	Up to 54	Not compatible with 802.11, 802.11b, 802.11g

DSSS: Direct Sequence Spread Spectrum

Ir: Infrared

OFDM: Orthogonal Frequency Division Multiplexing

CCK: Complementary Code Keying

PBCC: Packet Binary Convolution Coding

home. The HRFWG argues that the open SWAP specification will: a) enable interoperability among many different consumer electronic devices available from a large number of manufacturers; b) provide the flexibility and mobility of a wireless solution. This flexibility factor is paramount to creating complete home networks in the future. The HRFWG-Japan subcommittee of HRFWG set up committees to plan future versions of SWAP that address the support of a variety of wireless multimedia applications being deployed at home (CEBus 2006).

Network Address Translation (NAT) Access Routers. The rapid growth of the Internet (including the adoption of numerous home and business networks) is causing IP addresses to be consumed at a fast pace. Prior to the advent of Internet protocol version 6 (IPv6) (which was designed to solve the shortage of IP addresses), the network address translation (NAT) (Egevang et al. 1994) technology was developed to conserve IP addresses. In recent years, NAT technology deployments have experienced an explosive growth and the NAT technology has been incorporated into various business and home broadband routers. A NAT-enabled router allows an entire non-routable range of network addresses to be hidden behind a single, unique routable “public” IP address (i.e., the address of the router itself). The NAT router is given two IP addresses: one non-routable IP address (that of the private local network) and

one routable (for the public Internet assigned by an Internet service provider for example) (Dutcher 2001). In the context of a home network, NAT maps all private IP addresses of devices residing on the local home network to the single public IP address (supplied by an the Internet service provider) of the NAT router. All devices on the home network can therefore access the Internet simultaneously by sharing the Internet connection through the NAT-based router. In addition, because NAT works by snooping incoming and outgoing IP packets, it can enhance network security of the local home network by limiting access of external hosts to the private home network. External hosts can only communicate with those hosts residing behind a NAT router that have initiated sessions with them. Incoming network traffic to the NAT router without a prior outbound request made from a local host is simply ignored. NAT can support either fixed or dynamic mappings of one or more internal and external IP addresses and has been implemented in hardware products (such as routers) and software products (such as Microsoft’s Internet Connection Sharing) (Microsoft 2006) that are being widely deployed in home networks.

Middleware Technologies

Several middleware technologies have emerged on the market recently. Most of them incorporate service

discovery protocols and architectures to facilitate highly dynamic cooperation among devices/services with minimal administration and human intervention. Common features supported by various middleware technologies such as universal plug and play (UPnP), JoIN-In (JINI), and others include: the ability to announce device/service presence to the network, automatic discovery of devices in the neighborhood and those located remotely, the ability to describe device capabilities as well as query/understand the capabilities of other devices, seamless interoperability with other devices wherever possible, and self-configuration with minimal administrative intervention. All these features make middleware technology an important software substrate over which home networking users can run their applications independent of the underlying hardware platforms. We now present some popular middleware technologies that can be deployed in home networks.

Universal Plug and Play (UPnP)

UPnP (UPnP Forum 2000a) is an architecture for pervasive peer-to-peer network connectivity of intelligent appliances, wireless devices, and PCs of all form factors. UPnP is designed to bring easy-to-use, flexible, standards-based connectivity to ad-hoc or unmanaged networks whether in home, small businesses, public spaces, or connected to the Internet. UPnP is independent of any particular operating system, programming language, or physical medium. UPnP allows a device to dynamically join a network, obtain an IP address, convey its capabilities, and learn about the presence and capabilities of other devices. The addresses of the UPnP devices can be hardwired or obtained from a DHCP server, or devices can use Auto IP to assign an IP address. Auto IP is a new draft of the IETF (Internet Engineering Task Force) standard that allows dynamic configuration of IPv4 addresses. Auto IP permits a UPnP device to select an IP address from a range of nonroutable addresses.

UPnP is a distributed, open networking architecture that leverages transport control protocol/Internet protocol (TCP/IP) and the Web technologies to enable seamless proximity networking. In addition to supporting control and data transfer among networked devices, UPnP is designed to support zero-configuration and automatic discovery for a wide range of device categories possibly from different vendors.

UPnP devices have embedded functions called “services.” Services can include turning off the device, scanning inputs for data, or similar functions. A UPnP network node can be a device, or a control point, or both. Devices have services that a control point can monitor or control. A control point in a UPnP network is capable of discovering and controlling other devices. After discovery, a control point could retrieve the device description and get a list of associated services, retrieve service descriptions for interesting services, invoke actions to control the service, and subscribe to the service’s event source. Anytime the state of the service changes, the event server will send an event to the control point. Devices can incorporate control point functionality to enable true peer-to-peer networking.

UPnP-enabled devices or control points have six layers of functions (UPnP 2000b). Layers 0, 1, and 2 corresponding

to addressing, discovery, and description respectively are fundamental; they exist in all devices and control points. Layers 3, 4, and 5 corresponding to control, eventing, and presentation respectively are optional. Control points can initiate an action on a device and send a control message using the definitions from the device-description document. To exchange information, the control layer uses a W3C (World Wide Web Consortium) draft standard, and the simple object access protocol (SOAP), which is a lightweight, eXtensible markup language-based (XML-based) protocol for exchange of information in a decentralized, distributed environment. The device completes the action and responds using SOAP.

The event-messaging layer relies on a basic push model in which control points listen for notifications of UPnP device state changes. To obtain event messages, control points subscribe to event messages for a specific service within a device. A network can contain multiple control points and multiple UPnP-enabled devices. A control point might want to listen to more than one network service but not all of them. By subscribing and unsubscribing to events, control points can be selective. When a service within a device has an event, it notifies all current subscribers. Consequently, all subscribers have current knowledge of the state of the device. Event messages use the general event notification architecture (GENA), an extension to the hypertext transfer protocol (HTTP) defined by the IETF draft standard. GENA is designed to send and receive notifications using HTTP over TCP and UDP. The presentation function presents information and control to the user. Presentation requires the completion of layers 0, 1, and 2: getting an address, discovering the device, and obtaining the device description. The description document provides the device URL for the presentation page for the device. A more in-depth discussion of the UPnP architecture can be found in (UPnP 2000a; UPnP 2000b; Lee and Helal 2002).

Join-in (JINI)

Jini (Sun Microsystems 2006a; Sun Microsystems 2006b), from Sun Microsystems, is a framework based on the idea of federating groups of users and the resources required by those users. The focus of the framework is to make the network a more dynamic entity that better reflects the dynamic nature of the workgroup by enabling the ability to add and delete services flexibly. Jini systems provide mechanisms for service construction, lookup, communication, and use in a distributed system. Examples of entities providing such services include devices such as printers, displays, or disks; software such as applications or utilities; information such as databases and files. The heart of the Jini system is a trio of protocols called discovery, join, and lookup. A pair of these protocols (discovery/join) occurs when a device is plugged in. Discovery occurs when a service is looking for a lookup service with which to register. Join takes place when a service has located a lookup service and wishes to join it, whereas lookup occurs when a client or a user needs to locate and invoke a service described by its interface type (written in the Java programming language) and possibly, other attributes. The following steps describe what interactions are needed among a client, a service provider, and a lookup service

for a service to be used by the client in a Jini community (Sun Microsystems 2006b; Sun Microsystems 2006). First, a service provider locates a lookup service by multicasting a request on the local network or a remote lookup service known to it. Second, the service provider registers a service object and its service attributes with the lookup service. This service object includes methods that users and applications will invoke to execute the service, along with any other descriptive attributes. Third, a client requests a service by Java type and, perhaps, other service attributes. A copy of the service object is moved to the client. Finally, the client interacts directly with the service provider via the service object (Edwards 1999). Thus, Jini provides an infrastructure and a programming model that address the fundamental issues of how devices connect with each other to form an impromptu community. Jini is based on Java technology and exploits Java remote method invocation (RMI) protocol (which in turn rely on TCP/IP support) to move code around the network. Home networks can exploit Jini to support specific device communities (e.g., devices constituting an entertainment network in the home).

JetSend

JetSend (Meadows 2000; HP 1999) is a media-independent peer-to-peer information exchange protocol developed by Hewlett Packard to provide interoperability among various kinds of devices. Existing point-to-point protocols do not fully describe the content of the information being exchanged making the data transferred both machine and operating system dependent. The protocol allows devices to connect to each other, negotiate data types, and exchange information. JetSend can exchange information in its proper context without any product-specific knowledge or device drivers. This capability enables a variety of embedded devices such as digital cameras, cell phones, scanners, and so on to exchange data with each other without knowing about the protocol being used to transfer the data. Another strong motivation that is pushing the adoption of JetSend is its availability in many of the devices mentioned earlier. For instance, all Hewlett Packard's standalone printers and scanners support JetSend.

In JetSend, all information is stored as *electronic material* in areas called *surfaces*. Each surface object has a name, a description, and content. The description is similar to a file header and contains information about the type and content of the surface. The content may be null, data or a link to some other surface. The data contained in a surface is called electronic material (e-material) (Meadows 2000). JetSend devices exchange information with each other using versions of surfaces (i.e., impressions that are not necessarily identical copies of the original surface). The main benefit of JetSend is that impressions need not be exact copies of the original surface. Instead, the impressions can be changed to ensure device compatibility. An example would be a digital camera that may have a surface containing a picture. The digital camera would send the picture to the printer by sending an impression of the surface containing the picture to the printer device for printing. In contrast to JetSend (where the digital camera directly communicates

with the digital printer), the traditional approach would have required a PC to be connected to the digital camera. The PC would then exploit some compatible digital camera application to receive the digital camera pictures and then prints the desired pictures using a compatible printer driver. The JetSend model removes the need of the PC and allows direct peer-to-peer connectivity between the digital camera and the printer.

To use JetSend to communicate, device-specific code must interact with an API composed of three main components namely, the *activity manager*, *interaction policies*, and *e-material routines*. The activity manager manages JetSend sessions between JetSend-enabled devices as well as the handling of events. Interaction policies control the type of interaction between devices using some types of policies. The e-material routines allow the device-specific code to format data to be communicated in a standard JetSend format for other JetSend-enabled devices to understand.

Home Audio Video interoperability (HAVi)

HAVi (HaVi 1999a; HAVi 1999b) is a digital audio/video (AV) networking initiative from several major consumer electronics companies, which is aimed at providing a home networking software specification for seamless interoperability among digital audio and video devices. Basically, HAVi allow functions of an audio or video device to be controlled from some other audio or video device regardless of the actual brands of these devices. Within a HAVi system, a device residing on the HAVi network is designed to have the capability of controlling other devices or being controlled by other devices. In other words, HAVi allows a device to be a controlling device and a controlled device simultaneously (there is no concept of a single master controller).

The HAVi platform running on HAVi devices is made up of several software modules that implement basic services such as network management, device abstraction, inter-device communication, and device user interface management. The HAVi specification defines a set of application programming interfaces (APIs) and system services to support the development of audio/video applications for the home network. The HAVi architecture is independent of any programming language, operating system, or CPU. This platform independence gives full flexibility to application developers and consumer electronics manufacturers to develop interoperable audio/video devices and applications. HAVi compliant devices automatically announce their presence and capabilities to other devices when they join the HAVi network without requiring any complex configuration and installation procedures—a featured often referred to as hot “plug-and-enjoy.” HAVi-compliant devices’ functionalities can be easily upgraded, via their dynamic device control modules, by simply downloading upgrades through the Internet. A device control module (DCM) is a software element that represents a single device on the HAVi network and makes available the device’s HAVi-defined APIs. Whenever a device joins or leaves the HAVi network, the device’s DCM is added or removed respectively by the DCM manager from the network (HAVi 1999b). Within a DCM, there are functional component modules (FCMs)

responsible for each controllable function within the device. All HAVi software elements communicate using a message passing mechanism. It is worthwhile mentioning that it is not necessary to use PCs to deploy a HAVi-based network.

The interconnection technology used by HAVi is the digital IEEE-1394 network. The high bandwidth capacity of IEEE 1394 makes it suitable to simultaneously handle multiple digital audio/video streams around the home (HaVi 1999a). The 1394 communication media manager enables software elements of the HAVi architecture to perform asynchronous and isochronous transfers over the IEEE-1394 network.

Open Service Gateway Initiative (OSGi)

The Open Service Gateway initiative (OSGi 2003; Gong 2001) is an independent, nonprofit industry group working to define and promote an open standard to connect smart consumer and business appliances to Internet-based services (Gong 2001). The complex diversity of home networking architectures and device technologies need to be coordinated to enable home users to fully exploit and reap their benefits. As mentioned earlier, management of these network architectures and services can become overly complex for home users. The advent of OSGi simplifies the management of home networks composed of multiple heterogeneous communication technologies. OSGi defines a collection of APIs split into a set of *core APIs* and a set of *optional APIs*. The core APIs support service delivery, dependency and life cycle management, resource management, remote service administration, and equipment management. All of the core APIs are either contributed by a member of the OSGi alliance or developed by OSGi technical working groups. The optional set of APIs refine mechanisms for client interaction and data management. In addition, several existing Java APIs are included in the optional services. OSGi leverages existing Java standards such as Jini and Java database connectivity (JDBC). This includes JDBC and several other Java standards. OSGi technical working groups also focus on integrating non-Java-based standards into the OSGi framework (Condry et al. 1999). OSGi specifies a framework (similar in functionality to an application server) where it is possible to dynamically load and manage software components also known as *service bundles* (OSGi 2003). These bundles can be instantiated by OSGi to implement specific services required.

The ability for devices to self-configure is particularly important in home networks because most home users and consumers do not want and cannot be expected to manually configure and administer the home networked devices. Device and service discovery technologies, such as the UPnP, Jini, and HAVi discussed earlier, all enable automatic self-configuration of devices. However, each of these technologies assumes the use of its specific set of homogeneous protocols. For example, a Jini device can only communicate with another Jini device on the Jini network using the Jini device discovery protocol. It is not possible for a Jini device (residing on a Jini network) to communicate with a UPnP device residing on a UPnP network. OSGi can be used to serve as a platform to interconnect the Jini and the UPnP networks, thereby enabling the Jini

device to seamlessly communicate with a UPnP network. By serving as the “glue” that allows various discovery protocols to interact with one another, OSGi promotes ease of use for the home network’s end users, who need not be concerned with the underlying protocols supported by the devices in their home networks. Moreover, OSGi also allows device manufacturers to implement protocols that are most appropriate for their devices, because the OSGi discovery APIs allow devices to interact not only with other devices that support the same protocols, but also with devices that support different protocols (such as between Jini and UPnP).

The device access specification (DAS) of OSGi allows multiple devices to be discovered and their services advertised, thereby making these services available to other devices, services, and applications. Integration of discovery technologies with OSGi is based on an import/export model. Briefly, registered OSGi devices and services are exported out of the OSGi framework. For instance, an OSGi printing service can be exported to a Jini network to appear as a Jini printer. Similarly, devices and services found by native discovery techniques can also be imported into the OSGi framework to appear as valid OSGi entities and accessible to other OSGi entities. It is this importing/exporting feature that allows cross-technology discovery and promotes interoperability among multiple device types (Dobrev et al. 2002).

Some of the main benefits of OSGi can be summarized as follows (Marples and Kriens 2001):

- a. *Platform and application independence*: The OSGi software environment can be implemented on different types of platforms and is applicable to different computing environments; this independence gives considerable freedom and flexibility to application developers and designers in their service offerings.
- b. *Multiple service support*: OSGi environments allow multiple applications from different service providers to coexist on one single service platform.
- c. *Service collaboration support*: OSGi services deployed can provide support to other OSGi services. Applications dynamically discover these services and can adapt their behavior based on the configuration of the environment and services that are present.
- d. *Network choice*: OSGi does not require the use of any specific network technology for communication.
- e. *Security*: OSGi has in-built security features that allow the concurrent support of services from different service providers to be supported. Many of these benefits of OSGi will simplify the management and deployment of home networks and services in terms of shared Internet access, energy management, security (alarm systems), remote healthcare, entertainment, and others.

Several software vendors have been developing OSGi-compliant products. Some of the prominent implementations that have emerged include the Gatespace Distributed Service Platform (Gatespace 2006), the service management framework (SMF) Micro Edition from IBM, mBedded server from Prosyst (Prosyst 2006), and lamp embedded server from Acronet (Chemishkian 2002).

Zero Configuration (ZeroConf) Technology

The IETF Zero Configuration Networking (Zeroconf) Working Group (IETF 2006) was chartered in September 1999. The goal of Zeroconf is to enable networking without requiring any configuration and administration. Zeroconf networking is particularly attractive for those environments where administration is impractical or impossible (Steinberg and Cheshire 2005). Common situations where Zeroconf technology can be of tremendous benefit include the home, embedded systems “plugged together” as in an automobile, or for impromptu networks such those set up between the devices of strangers with a view of collaborating with each other. There is tremendous potential for Zeroconf in the home networking area, because home owners often do not want to be burdened by configuration and administration tasks often associated with networked devices. It is worth noting that although one of the goals of Zeroconf networking is to make personal computer networking easier to use, the long-term objective is really to enable the creation of entirely new kinds of networked products, products that today would simply not be commercially viable because of the inconvenience and support costs involved in setting up, configuring, and maintaining a network to allow them to operate. AppleTalk users are already familiar with the benefits provided with such technology because the Mac operating system incorporates the Rendezvous technology to support zero configuration over standard IP protocol for automatic discovery of computers, devices, and services. Microsoft’s NetBIOS software interface also provides similar capabilities over TCP/IP. Recent efforts of the IETF Working Group on Zeroconf (Zero Configuration Networking) have been focusing on standardization issues. Once Zeroconf protocols are standardized and implemented into commercial network products, they will play an important role in the future deployments of networked homes.

Remote Internet Access to Home Networks

Home networks enable users to get information about the home’s condition, to remotely control home systems and appliances, and to gain access to information and entertainment resources both from inside (such as a

computer hard drive) and outside the home (for instance, from the Internet) (Rose 2001). To provide these benefits to home consumers, different devices of the home network must be able to communicate with each other to provide services despite their implementation differences. This requires the management and coordination of discovery methods that work across heterogeneous device technologies and complex home networking architectures. To achieve this management and coordination transparently without user intervention is a complex task which, until now has been the major factor responsible for impeding the wide acceptance and delivery of advanced services into the home. A common solution is to exploit a central connection point often referred to as a **residential gateway** (Bull et al. 2004; Marples and Kriens 2001). The gateway manages the home network by hiding the complexity of various heterogeneous communication technologies (e.g., phoneline, powerline, HomeRF) from home users. The residential gateway also acts as a “bridge” between the wide area network (e.g., Internet) and the home network (as illustrated in Figure 3), thereby giving users access to home devices and control over the information exchanged among these devices.

Desired Characteristics of Residential Gateways

As mentioned previously, a residential gateway plays a central role in home networks in acting as a central coordination point for various home devices as well enabling remote access to the home network. The residential gateway also acts as a point of entry where services can be installed and managed by service providers. Since a residential gateway is responsible for many such crucial functions, it is important that the gateway device has some desired characteristics. We enumerate some of these desired features (Gong 2001; Condry et al. 1999; Tsai et al. 2004) below:

- **Platform and vendor independence:** residential gateways should be designed and programmed to be both platform and vendor independent so that service developers would not have to spend time porting their services. Achieving this independence requires gateway implementations from different vendors to exploit open,

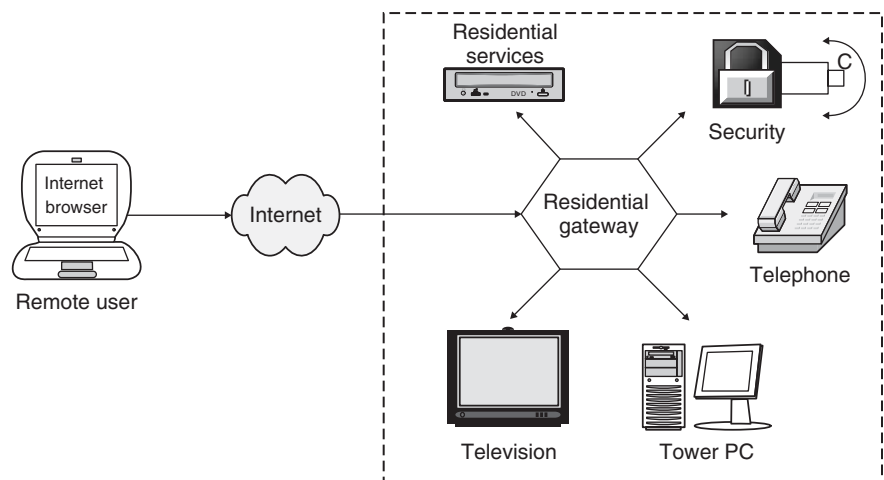

Figure 3: Residential gateway access to the home network

standard APIs so that the gateways can support services developed by different, independent software vendors.

- **Maintenance and upgradeability:** by conforming to some open standard (such as an API), home network users should not be required to change their residential gateways when their service providers change. It should be simple and easy to make dynamic upgrades of residential gateways to support new services or enhance existing services cost-effectively.
- **Integration and interoperability:** residential gateways should be capable of supporting heterogeneous network and device access technologies (for example, interoperability between a Jini-enabled camera and a UPnP-enabled display device) seamlessly.

Other typical residential gateway characteristics may include zero administration, limited memory and computation requirements (Condry et al. 1999).

Quality of Service-based (QoS-based) Residential Gateways. For several years, home networking users have been focusing primarily on computing-based applications using PCs and peripherals (printer, scanner). However, with the emergence of technologies such as HAVi and IEEE-1394, we have witnessed a shift towards entertainment-centric devices being installed and deployed over home networks. Most of these entertainment appliances and devices generate and handle high-quality, high-bandwidth audio/video streams over the home network.

To ensure the delivery of guaranteed performance over home networks for bandwidth-sensitive and delay-sensitive multimedia applications, we need efficient resource management techniques to be in place. These techniques should provide dynamic bandwidth allocation to devices and services based on their service requirement to deliver optimal performance to home users (Lei et al. 2002). It is worthwhile to mention two approaches that have recently been proposed to address the resource management issue in home networks:

- One approach is the adaptive resource management system (Okamura 2001) for home networks proposed by Okamura from Sony Laboratories Inc. Okamura's resource management approach (demonstrated by a prototype system called PPS/J) exploits dynamic adaptation mechanisms by allowing poor devices (for example, PDAs, cellular phones), with limited computational resources (such as memory, CPU power, and disk space), to borrow surplus of computational resources from rich devices (for example, PCs).
- Another approach proposed by Lei et al. (2002) exploits the notion of *Quality of Service-aware* (QoS-aware) *residential gateways* beneficial for both service providers and home consumers. From a service provider perspective, a QoS-aware residential gateway provides more attractive services in that the provider can charge home network users according to the quality level of the service delivered to actual home devices. Home network users also fully benefit from a QoS-aware residential gateway in the sense that the available home network bandwidth can be optimally distributed to different

home networked devices according to their individual bandwidth requirements.

Web Access to Home Network Devices with Handheld Devices

To facilitate access to home network devices anytime, anywhere using small, portable handheld devices such as Web-enabled cellphones, PDAs, and other mobile handheld devices, the wireless application protocol (WAP) is often used. WAP defines the wireless markup language (WML) and WMLScript for mobile applications to display Web content by addressing the limitations of small screens in mobile clients. One of the key components of a WAP-based network is the WAP gateway (Ma and Irvine 2002) which is connected to the Web. The function of the WAP gateway is to provide operator specific services or to perform content and protocol translation between TCP/IP and the WAP stack. The WAP gateway also resolves domain names to IP addresses by performing all required domain name server (DNS) services, and translates Web pages into compact encoded formats that reduce the size and number of packets required to be transmitted over the wireless communications network. The result of these operations is to offload many TCP/IP functions from phones, and PDAs, enabling these devices to be smaller, less powerful, requiring less memory resulting in lower-cost of producing these devices. User interaction with the WAP gateway is initiated through the WAP browser. The terminal sends its request to the WAP gateway, which then requests the content from the Web server.

In the case of mobile Internet applications, data transfer speeds are low, and mobile handheld devices are much slower compared to computers connected to fixed, wired networks. Moreover, these devices typically have small screens and require that the Web content be displayed differently from the display on typical personal computers. WAP (Aust et al. 2002) is a protocol designed to specifically transmit Web-like content to mobile phones and other (usually wireless) devices with low bandwidth access (Saha et al. 2001).

A WAP-enabled handheld device can access Web sites similar to personal computers connected to the Internet by sending WAP requests to the WAP gateway. Using WAP, a small, portable device views Internet information that is presented in a format to suit the device's screen. Web browsing over the Internet uses HTTP to transport the Web pages and the language that defines the manner by which content is displayed is the hypertext markup language (HTML). Thus, to view the HTML pages associated with home network devices, we need to convert HTML pages to WML pages dynamically. By dynamically converting HTML to WML, we eliminate the need for having an HTML version and a WML version of the same Web site. Dynamic conversion of HTML to WML can be achieved using the following approaches:

- **WAP gateway** (Deri 2001): a plug-in at the WAP gateway can perform the necessary dynamic HTML to WML conversion. The WAP Gateway receives the request (in WML) from the WAP client for a particular HTML page. The gateway contacts the necessary Web server for that

page using TCP/IP. After obtaining the HTML page, the WAP gateway runs a program (Perl or JavaScript) that converts the HTML to WML on-the-fly and forwards the converted WML file to the WAP client. The WAP gateway approach takes control away from Web content providers since they will have to rely on WAP gateways to provide this plug-in to make their Web sites accessible to small, portable, mobile devices. Alternatively, the content provider will have to provide a WML version of their site, which increases costs.

- **WAP browser:** a WAP Browser add-in that converts HTML to WML on-the-fly can also be used (Vantroys and Rouillard 2002). The disadvantage of this solution is that it increases resource demands on the small mobile devices that already lack resources. Thus, such a solution is ineffective.
- **Web server:** software such as the *mobile converters* could be added to Web servers (Christianson et al. 2002) to make the servers capable of distinguishing between requests from WAP and those from regular Web browsers. Depending on the source of the request, the Web server will either serve a WML or an HTML page. This solution is effective but it requires all Web servers to have the plug-in for it to be efficient. With this approach, the WAP gateway and Web server functionalities are merged together.

It is worthwhile noting that two common methods of implementing the dynamic conversion of HTML to WML include: a) *using Perl scripts* (Vanderdonckt et al. 2001): there are a few Perl scripts available that convert HTML to WML. The Perl script formats a WML page by ignoring tags in HTML that are allowed in WML and replaces those that are not with the corresponding WML tags (for instance, replacing the body tag in HTML with the card tag for WML); b) *using XSLT (eXtensible stylesheet language transformation)*—a language for transforming one XML document into another XML document. XSLT is designed for use as part of eXtensible stylesheet language (XSL), which is a style sheet for XML (Forstadius and Loytynoja, 2001). Given that an HTML document is not governed by strict standards and rules, it cannot be directly converted into a WML document. It has to be first parsed into an XHTML or XML document by using a tool such as tidy.exe and then converted into WML using XSLT. Tidy.exe is a HTML tool that was originally written by Dave Raggett of the World Wide Web Consortium (W3C). It is designed to fix mistakes in HTML, tidy up the layout, assist with web accessibility, and convert HTML to XHTML (Tsymbalenko and Munson 2001).

The various approaches discussed above can be used to convert HTML to WML to enable small portable device users to access and operate home network devices remotely. We argue that the most efficient solution is to place the HTML to WML converter at the WAP gateway. This approach yields two main benefits namely: a) it allows the converter to use gateway resources and will not place resource demands on the limited resources of small, portable handheld devices, and b) no changes are required by users of WAP-enabled devices and Web server administrators.

It is imperative that manufacturers of home control systems continue to develop Web-accessible home devices and appliances to enable home users to access their home networks locally or remotely via highly mobile devices such as PDAs and WAP-enabled phones. WebLink software, developed by Home Automation Inc. (HAI) (one of the first companies to exploit Web access to home networks), provides users home device functions displayed through Web pages.

RELATED WORK AND CHALLENGES OF HOME NETWORKS

Related Research

Many researchers are working on various components of home networks. Some of recent research efforts such as the PPS/J prototype system developed by Okumara (Okamura 2001) and the QoS-aware residential gateway developed by Lei et al. (2002) have already been discussed. Saif et al. (2001) discussed the design and implementation of a residential gateway in the context of the Auto-Han project. As mentioned earlier, the OSGi expert group (OSGi 2003) is currently focusing on the development of drivers for all possible and probable protocols to be used in home networks. Several research groups have been exploiting OSGi technology to address many of the home networking challenges (such as interoperability, scalability). Dobrev et al. (2002) proposed a framework to extend the OSGi framework to enable redefining gateway services and to provide a smart querying technique for users and devices to look up services with particular attributes. The authors also addressed the interoperability feature and proposed implementing it through extensions of OSGi services. Wils and colleagues (Wils et al. 2002) proposes integration architectures for UPnP-based and Jini-based home network devices within an OSGi framework.

Rice University researchers recently proposed the Rice Everywhere Network (RENE) (AAzhang et al. 2006) architecture to explore the integration of wireless code division multiple access (W-CDMA) cellular systems, high-speed wireless local area networks, and home wireless networks. Their goal is to develop a seamless multi-tier network interface card (mNIC) that can interact with various radio frequency units (AAzhang and Cavallaro 2001).

Challenges of Home Networks

Until recently, home networking was being deployed mainly to allow multiple PCs in the home to share a single Internet connection. This trend has changed significantly in the last decade. Home networks are expected to provide additional capabilities including network-enabled devices such as digital audio/video servers, VoIP systems, security services, and others. Although it is true that these new systems enhance the value of added services, they also make their management and maintenance by (most inexperienced) home users difficult as their complexities increase with new added features. As a result, we must ensure that such complexities do not overburden home users to the extent that they are discouraged from adopting

home networks. It is therefore crucial that future home networks meet the following requirements:

- Home environments typically contain many heterogeneous devices and home users are unlikely to install significant new cabling to support a home network—lack of skills and the low desire to perform major network configuration or maintenance makes home networking deployment expensive. This means that configuring a home network and its maintenance should be simple and easy to do. A home network should support plug-and-work capabilities enabling new devices to join and leave the network without requiring any configuration whenever possible. Transparent mechanisms are needed to allow devices to advertise their services to other devices as well automatically discover other services from other home network devices.
- Seamless interoperability among devices remains a significant challenge in the deployment and operation of home networks. Open APIs and platform-independent representations need to be deployed to enable flexible modeling and optimal representations of devices, network states, device functions, and resource registration in the home network. Languages such as XML (W3C, 2006) and XSL (Adler 2000) can be deployed. Saif et al. (2001) discuss these issues in more depth in the Auto-Han project.
- Remote access to home networks is becoming an important feature. This trend is expected to continue with highly mobile users and the ubiquity of Internet access and the Web. Secure access to home networks will need to be implemented and deployed. A discussion of the security issues in home networks is beyond the scope of this work but is extensively covered in recent articles (Saif et al. 2001; Ellison 2002; Zhou et al. 2005).

The requirements above stem mainly from the fact that home network users have quite different expectations from traditional network environments. Many factors such as the ease of use of network, reliability, scalability, adherence to open standards, and cost will ultimately determine the adoption success and deployment of future home networks. Next generation home networks will be expected to support much higher resolution video terminals, networked appliances, different types of sensors, and various Internet terminals. To provide such support, novel home networking technologies (including network topology considerations, transmission medium, bandwidth control, residential gateway functionality and so on) need to be explored and developed (Seik 2004).

CONCLUSION

Over the last few years, we have experienced an explosive growth in the emergence of networking and computing technologies. The adoption and deployment of these technologies by end users are fueling new paradigms in our day-to-day activities in terms of the way we live, work, and communicate with each other. The home is one of the environments where we are currently witnessing the strong convergence of computing and communication. In this

work, we focused on home networking—an area that has generated a lot of interest among consumers, service providers, and manufacturers of home networking products. We have presented many of the technologies that have become available and can be used to design, develop, and deploy sophisticated, highly dynamic home networks cost-effectively. The actual implementations of home networks may vary depending on the choice of the underlying connection technology, middleware, or residential gateway design. However, we argue that most home networks will still need to satisfy the following fundamental goals such as efficient sharing of resources (including sharing of Internet access and devices such as printers, playback, and storage devices) anywhere in the home, seamless connectivity of computing, home automation, and entertainment home network clusters, and strong interoperability among different home devices, and finally support remote access to home devices from anywhere inside and outside the home. Finally, to conclude, we argue that the success and deployment of digital networked homes will ultimately depend on value-added services that become available to home consumers and their associated costs.

ACKNOWLEDGMENT

Many colleagues provided their great support and contributions during the preparation of this chapter. We express our deepest gratitude to Mohammad Saklayen for his time and efforts in providing us some of the materials presented in this chapter. We express our thanks to Priya Kubher for her input and ideas on the WAP protocol. We thank Nadeem Ansari and Srivatsan Krishnamurthy for their help on OSGi interoperability features and recent home networking efforts respectively. This work was supported by grants from Sun Microsystems (Palo Alto) (EDUD-7824-000145-US), Microsoft Corporation (Seattle), and Ixia Corporation (Calabasas). We are grateful to Farhan Siddiqui and the anonymous reviewers for their suggestions and comments on early drafts of this chapter. We would also like to express our high appreciation to the editor-in-chief, Hossein Bidgoli, for his patience, encouragements, and kind support throughout the preparation of this chapter.

GLOSSARY

Extensible Hypertext Markup Language: Hybrid between HTML and XML specifically designed for networked device displays.

Extensible Markup Language: A specification (designed especially for Web documents) developed by the World Wide Web Consortium (W3C).

Extensible Stylesheet Language Transformation: The language used in XSL style sheets to transform XML documents into other XML documents.

Home Audio/Video Interoperability: A standard, developed by several leading electronics and computer manufacturers, that allows a number of different home entertainment and communication devices to operate from a single controller device such as a TV set.

Home Network: Home networks facilitate communication among appliances, home systems, entertainment

products, and information devices in a home so that they can work cooperatively and share information.

HyperText Markup Language: The authoring language used to create World Wide Web documents.

HyperText Transfer Protocol: The underlying protocol used by the World Wide Web. HTTP defines how messages are formatted and transmitted and what actions Web servers and browsers should take in response to various commands.

Internet Protocol: The Internet Protocol (IP) is the method or protocol by which data is sent from one computer to another on the Internet.

Jini: Software from Sun Microsystems that seeks to simplify the connection and sharing of devices, such as printers and disk drives, on a network.

Middleware: A software layer residing between the operating system and applications. It is often used to support complex, distributed applications.

Network Address Translation (NAT): An IETF standard that enables a local area network (LAN) to use one set of IP addresses for internal traffic and a second set of addresses for external traffic.

Open Services Gateway Initiative: An industry plan for a standard way to connect devices such as home appliances and security systems to the Internet.

Residential Gateway: It is a device that connects the home network to the Internet. It also enables access to services (such as telephony, cable TV) delivered to the home.

Service Discovery Protocol: The service discovery protocol provides a mechanism for client applications to discover the existence of services provided by server applications as well as the attributes of those services.

Universal Plug and Play: A standard that uses Internet and Web protocols to enable devices such as PCs, peripherals, intelligent appliances, and wireless devices to be plugged into a network and automatically know about each other.

Wide Area Network: A network that spans over large distances; usually connects many other networks together.

Wireless Application Protocol: A specification that allows users to access information instantly via handheld wireless devices such as mobile phones, pagers, two-way radios, smart phones, and communicators.

Wireless Markup Language: An XML language used to specify content and user interface for WAP devices.

INTRODUCTION

The field of multimedia networking is primarily concerned with the study of efficient audio and video transport through computer networks. Optimal digital transport of these media requires a thorough understanding of human perception and psychology at the end points of communication and the implied methods to effectively encode media into digital form. Encoding formats such as MP3 for music, or MPEG-4 and Quicktime (Apple 2007) for video are household words today, but the development of new standards to represent media content with the greatest fidelity, least amount of loss, and the most compact space requirements never ceases. Multimedia transport also requires an integral understanding of the complex interplay between network components, protocols, and performance factors. In particular, the Internet was originally not designed to store and forward continuous, time-sensitive, and bulky media. The diversity of devices and links in Internet transport infrastructure, from pocket-sized personal digital assistants to powerful multiprocessor machines communicating across phone, cable, or optical media in an amalgam of wired or wireless links, creates a complex spectrum of network interdependencies, across which multimedia transport has to be managed.

With its native best-effort service, the Internet does not inherently provide the end-to-end delay guarantees required for multimedia transport. Multimedia content is generally large in size, media storage and transmission costs are significant, and thus media generally must be compressed for effective storage and streaming. Newer devices blur the line between personal computing and home entertainment appliances. Similarly, next generation cell

phones and “media pods” support television on-the-go and various modes of ad hoc multimedia information sharing. Along with these consumer market developments, network middleware for real-time transmission, media scaling, wireless media-supportive protocols, Quality-Of-Service (QoS), broadcasting or multicasting, and various forms of session support for small or large user groups are needed to augment the best-effort IP model and live up to the expectations associated with innovative networked media services. Recently, a complete redesign of the Internet to accommodate modern day communication requirements has been proposed (Clean Slate 2007).

This chapter discusses the principles of multimedia networking with focus on the network mechanics extending the Internet architecture to support the service requirements for multimedia through packet switching. Topics include human perception of multimedia content and their translation into network requirements for audio or video transport, packet-switching network service models for continuous and real-time media transmission, Quality-of-Service, streaming and synchronization protocols, multicast and content distribution, and the network middleware behind voice over IP and video over IP. Multimedia networking via asynchronous transfer mode (ATM, (see “ATM”)) or other circuit-switched methods has lost much ground during the past decade to packet-switched solutions, mostly as a result of the fact that packet switching is simpler and less expensive to build upon and deploy. Details on circuit-switched multimedia delivery will hence be omitted. In addition, other topics such as authoring of documents, media servers and storage models, audio/video encoding and compression, error control in multimedia transport, wireless multimedia specifics, or security aspects in multimedia transport will

Figure 1: Basic multimedia networking architecture

not be discussed. The chapter concludes with an outlook on future developments.

MULTIMEDIA AND NETWORKING

“Multimedia” represents the integrated use of discrete (text, graphics, images, slides) and continuous (audio, video) forms of expression to convey digital information more fully than it would be possible through a single-medium representation alone. Multimedia networking is thus concerned with the control and transmission of integrated audiovisual content across communication channels, which today primarily means the Internet. “Medium” signifies the form through which the content is captured, processed, represented, and transported. Figure 1 shows a basic multimedia architecture with one or more capturing devices feeding analog input, either live or from server storage, in digital form into a network, which carries it to one or more receivers, where the content is played out at once or archived in media servers for later access.

Major efforts have been made during the past decades in Internet-based multimedia research to mimic and expand the use of conventional multimedia to enrich communication in fields such as medicine, sports, education and research, or entertainment. Telephony and television, movie recording and editing, music composition, e-learning, and the pervasive use of multimedia through mobile devices are examples for applications undergoing a fundamental facelift in the digital domain. The Internet’s original purpose was to support data communication between computers. Today, the term “data” goes beyond early notions of discrete textual content, and encompasses multimedia in the widest sense. With increased computing power in network devices, greater bandwidth, and significant progress in network middleware (Duke and Herman 1998), the legacy Internet architecture is transforming into a federation of networks that natively encompass data, voice and video communications, reflecting the ITU-T definition of a next generation network (NGN) (ITU-T 2006). In contrast to classic data networking, multimedia networking incurs a much greater volume of data to be transferred. Network bandwidth, latency, media encoding, and device compatibility are a focal point in the development and deployment of networked multimedia applications.

Networking of multimedia can be supported in the network core with routers performing resource reservation and support for distinct media flows, in the transport layer with real-time supportive protocols, and at the network edge and in end-systems through overlay networks (Milic et al. 2005) and intelligent edge

routers. Besides bandwidth, the most critical factor for multimedia networking is time, in contrast to legacy data networking which is foremost concerned with transmission errors. Bandwidth over-provisioning may not solve the need for timeliness guarantees. While packet loss can be compensated (Perkins et al. 1998; Feamster and Balakrishnan 2002), end-hosts cannot correct late packets. Furthermore, the processing and transport of multiple media demands much computing power, storage, and bandwidth. The sheer volume of data, synergy among all computation and communication components, and the integrated transport of traditional, discrete information and continuous media across the best-effort Internet have posed many research challenges. Multimedia networking hence relies on a variety of protocols and network topologies to provide users with media-rich content across networks and devices with varying capabilities.

Brief History of Multimedia Networking

The history of multimedia networking is intertwined with the history of real-time computing. However, where real-time computing is concerned with fault tolerance, scheduling and deadlines, multimedia networking adds bandwidth requirements and puts less weight on fault tolerance. The origins of this field can be traced back to the early developments in continuous media transmission, such as the AT & T Picturephone video conferencing systems (Lipartito 2003) in the late sixties, the network voice protocol (NVP) implemented in 1973 (RFC 741), early efforts on streaming with the ST-II protocol (RFC 1190), or the MIME extension format (RFC 1521) to attach multimedia content to e-mail. The ARPANET development of NVP laid the foundation for today’s voice over IP (VoIP) technology: “. . . to demonstrate a digital high-quality, low-bandwidth, secure voice handling capability as part of the general military requirement for worldwide secure voice communication.” (RFC 741) With the rapid improvement of personal computing and networking since the 1970s, information processing on computers has evolved from basic text-based representation to a rich mixture of media. The paradigm of standalone desktop computing has long been replaced by distributed computing and internetworking and traditional circuit-switched telecommunication is gradually displaced by packet-switching to transport images, voice and video across computer networks.

Traditionally, voice has been carried over telephone networks, video over cable networks, and data over computer networks. Early networking operated on a purely textual basis, but postal deregulation, private networking, the first digital PBXs and voice-mail innovations shifted networking into a voice-centric services model in the late 1970s and early 1980s. The first paper on speech compression for packet-switched transport was published in 1973 (Magill 1973) and in 1978, U.S. patent 4,100,377 was granted for “Packet Transmission of Speech.” The late 1980s and early 1990s integrated data and voice communication with desktop computing, local area networking, public network data services, and commoditized voice technologies (Ziegler et al. 1989). In 1990, the ITU issued the G.764 recommendation for voice packetization and packetized voice protocols. Shortly thereafter the first IETF audio-cast

over the multicast backbone (MBone) took place (Casper and Deering 1992). The MBone was built as an overlay network dedicated to IP multicast experiments. For greater scalability, IP multicast (see "IP Multicast") offers a solution to transmit a single stream across multicast-capable routers from one source to many receivers, where routers only replicate stream packets at junctures leading to downstream subscribers. In 1996, U.S. patent 5,526,353 was granted for a method to transmit packet audio over a computer network, offering a solution for temporal synchronization of data packets relative to their position in an audio stream. Although earlier experiments used special-purpose hardware and low-bit-rate encodings, new experimental interest for transmitting voice over packet networks arose after Sun Microsystems introduced the SPARCstation 1 with built-in μ -law audio codec.

The early 1990s also produced asynchronous transfer mode (ATM), a circuit-switching technology and connection-oriented network protocol encoding data into small fixed-sized (53 byte; 48 bytes of data and 5 bytes of header information) cells, developed in contrast to variable sized frames used in packet-switched networks. The most recent stage of multi-service network evolution brought innovation in integrated data, voice and video communication, more sophisticated Layer-3+ network services, virtual private networking and significant convergence of services in the industry. These developments mark a departure from traditional circuit-based communication to packet and cell-based infrastructures. Increasingly sophisticated convergence devices integrating telephone, TV, radio, and personal computing functions are constantly emerging in this marriage of multimedia, telecommunications, and computer networking technologies. With the World Wide Web as a platform for hyperlinked sharing of multimedia content, current research and development tackles PC-to-phone applications for scalable and low-cost voice communication, as well as video and TV applications through the Internet.

Despite these efforts to bring high-quality media distribution to user's fingertips, a common network-integrated multimedia infrastructure as shown in Figure 2, which allows seamless and scalable access to content across different platforms, whether mobile or desktop, small-scale or large, is still the focus of interdisciplinary research and development. Such complete integration of the multimedia PC with the smart home, house appliances, PDAs, laptops, digital photography, mobile music players, cell phones, recording devices, GPS, the home stereo and many other gizmos is the ultimate vision for a media-rich, network-augmented digital lifestyle.

Multimedia Characteristics

All media can be regarded as a special type of digital data. Transmission of graphics, music, photos, and video ultimately always results in a sequence of bits being carried across networks, however, the process and quality of multimedia networking is shaped by various factors:

- Perception: what senses are being used to perceive the media
- Representation: how are the media encoded
- Presentation: how are media recorded and formatted
- Storage: how and where are the media archived
- Transmission: what carrier type, distribution topology, and protocols are used for media transport

Media can be classified according to whether their representation is primarily a function of space or time, and whether they are created through recording or synthesis (Table 1.) Text or graphics are discrete media typically created on the computer, while photos are typically captured. For both media types, their spatial properties are critical for correct processing. Transmission of GIF and

Figure 2: Integrated multimedia networking architecture

Table 1: Media Classification

Synthesized	Text, Graphics	Animation
	Still Images	Audio, Video
Captured	Discrete / Spatial	Continuous / Temporal

TIFF graphic files, or JPEG photos across networks is hence a matter of spatial representation and compression. As soon as the time of creation, mixing, or transmission becomes a critical factor in timely processing or reception, media can be categorized to be of temporal nature. This is the case for continuous media such as audio and video, which are captured and typically streamed, in contrast to animation, which is synthesized. Hybrids are possible, for example, when meta-data such as the creation date of a digital camera photo become important for network sharing, or when digital images are touched up with digital photography tools.

On the other hand, although numerous standards for continuous media encoding and compression (see “Image Compression,” “Video Compression,” and “Speech and Audio Compression”) exist, such as MP3, Ogg, AAC, FLAC, or WMA for audio, or MPEG-1, MPEG-2, MPEG-4, DivX, or WMV for video, scalable and high-quality transmission of continuous media has been the core technical challenge in multimedia networking research since the inception of the field. The primary factor for multimedia transport beyond any encoding and compression technology, however, is simply network bandwidth. Bandwidth in the context of the Internet refers to the channel capacity or bit rate of a link (Crowcroft 2000). However, independent of technical capacities, the amount of bandwidth needed to transmit multimedia ultimately depends on processing and perception constraints, as well as quality expectations at the users’ end. Table 2 contrasts data, pure voice, and mixed media traffic in terms of network characteristics. It shows that multimedia traffic has the highest complexity.

Human Perception and Multimedia Representation

Transmission constraints are dictated by the amount and quality of the media, and the perceptual constraints (Steinmetz 1996) of the human senses. Protocol design for real-time multimedia traffic should maximize the user-perceived quality in media transport while eliminating redundancy. Although the eyes respond to stronger signals or higher frequencies with cumulative reaction, the ears operate on a logarithmic scale. For audio, this means resolution in terms of sampling rate and quantization. The human ear, as a differentiating apparatus, perceives sound as a function of signal strength and frequency in the range of about 50 Hz to 20 kHz. Human speech and voice transport is limited to the 1 to 4 kHz range. Traditional copper wires were hence deployed for the purpose to carry baseband signals and “toll” speech quality audio with a bandwidth of 4 kHz. According to the Nyquist theorem, the sampling rate for voice is 8 kHz, and with 8 bits per sample, one voice conversation requires hence a minimum of 64 kbps. Two such conversations constitute the bandwidth of integrated services digital network (ISDN) connections.

The human eye on the other side is an integrating apparatus and sets video transmission constraints as a function of the resolution in pixels, bits per pixel, color space, and the frame rate. *Perceptual coding* exploits the strengths and flaws of the human auditory and visual system to filter out the relevant and mask the irrelevant. The resulting coding and compression schemes help to save bandwidth by filtering out information that contributes the least to the perceived quality of media by eliminating temporal redundancy and exploiting common patterns. For instance, knowledge of the threshold for audibility in the human ear for any frequency allows to mask weaker sounds in the shadow of stronger ones, or to omit sound from encoding if its falls below this audibility threshold. Once media are recorded and encoded observing perceptual qualities with a given frame rate, sampling frequency or quantization level or resolution, a certain minimum bandwidth is needed to carry the media across a network.

Table 2: Comparison of Traffic Types

	Data	Voice	Multimedia
Data Rate	Low	Low - Medium	High
Traffic Pattern	Bursty	Streamed	Streamed/Bursty
Loss Tolerance	None	Some	Some
Latency Constraints	None	Small (30ms)	Small
Connectivity	1-1	1-1	1-1, 1-n
Temporal	None	Synchronized	Synchronized
Service	Single Flow	Single Flow	Multiple Flows

The Role of the Multimedia Operating System

Integration of networked multimedia services with the operating system (OS) kernel is crucial for performance and interoperability. The multimedia OS (Steinmetz 1995) is quite similar to a real-time OS, because applications in both cases require predictable service and the ability to provide firm performance guarantees. However, the multimedia OS should operate from a *communication-oriented*, rather than computation-oriented perspective, offer *scalability* to facilitate among autonomous devices such as a networked camera, a set-top box controlling TV, and other home devices, and remain *extensible* to processor enhancements and future devices. In particular, the performance of the I/O subsystem is paramount for the massive amounts of data, as handled for example by multimedia servers (Gemmell et al. 1995). After various forerunners, such as the BeOS and NeXTstep, dominant operating systems of today such as Linux, Apple OS, and Windows come now with increasingly powerful, integrated multimedia capabilities.

Figure 3 shows the interplay between the various layers in a multimedia services stack, in correspondence to a network middleware model for multimedia applications. Networked devices interact with each other via the network layer, running media-centric applications to exchange content. This four layer model coarsely correlates with a TCP stack. The network middleware provides the glue between media and applications among two communicating devices, and includes codecs, component management, file management, media management, and an interface to network services such as sockets, enabling multimedia applications to interoperate.

Network Requirements for Multimedia Traffic

Network bandwidth is in constant need for growth as a result of the all-in-one convergence of data, voice, and video transport. The dimensions by which carrier systems are assessed in their capacity are rooted in the notion of how many voice flows can be routed through a data network. The stacked capacities of the T-carrier system in

Figure 3: Multimedia stack and middleware abstraction

the United States and the European E-carrier system are based on the fact that one voice conversation through a digital medium requires a bandwidth of 64 kbps (Leon-Garcia 2001). In the T1 system, analog signals are sampled 8,000 times per second and each sample is digitized into 8-bit quanta. With 24 channels digitized in parallel, a 193-bit frame is hence transmitted, with one single bit as frame separator. The 192 bit frame multiplied by 8,000 and the additional 8,000 framing bits result in the T1's 1.544 Mbps data rate. The signaling bits are the least significant bits in each frame. An integrated T1 line can serve a different application on each channel. Higher capacity channels in the digital signaling hierarchy are multiples of T1 capacities. For instance, a T3 connection supports 672 conversation channels at a cumulative rate of 44.736 Mbps.

Table 3 compares the bandwidth requirements for common types of audio and video applications, from low-quality audio to tele-immersive applications. It shows that higher quality media distribution is currently only possible with powerful compression. The bit rate is a simple metric for required network bandwidth, but does not directly correlate with the actual quality of the transmitted media. For details on transmission requirements for other media types such as images and graphics, see Halsall (2000).

NETWORK SERVICES FOR MULTIMEDIA TRANSMISSION

Distribution of multimedia content entails media packetization for transport through datagram networks, multicast, content distribution networks, synchronization and scaling of media, Quality-of-Service, and the need for congestion control and fairness in transmitting multimedia alongside regular TCP connections.

Packetization

The raw digitized sound bit rate is not exactly the network bit rate, because packet headers add extra control bits to each packet. Packet headers for audio transport typically include the audio format, an identifier marking the conversation or flow that the packet belongs to, a timestamp and sequence number, and synchronization information. The realtime transport protocol (RTP) header typically adds 12 bytes to the packet, the UDP header adds 8 bytes for transport, and the IP header adds 20 bytes. For example, a raw G.711 stream of 64 Kbps effectively requires between 68 and 80 Kbps, but silence periods in speech can be used to compact the stream and decrease the nominal bit rate. Various ideas have been proposed to align application-layer semantics with IP packet processing for improved efficiency. The *application level framing* (ALF) principle (Clark and Tennenhouse 1990) states that networking mechanisms should be coordinated with application-level objectives, which is inherently difficult, since packet flows may incur inter-stream tradeoffs if they do not share a complete end-to-end path. ALF helps to coordinate the behavior of heterogeneous protocols distributed among various devices by incorporating knowledge to reflect the application-level semantics in

Table 3: Multimedia Transmission Characteristics

Media	Format	Uncompressed	Compressed
Telephone low	G.728 LD-CELP	16 Kbps	
Telephone standard	G.711 PCM	64 Kbps	
Telephone improved	G.722 SB-ADPCM	48–64 Kbps	
CD stereo	WAV	1410 Kbps	
CD surround (5.1)	MPEG-2, DTS		320 Kbps
DAT (Digital Audio Tape)	DAT	1636 Kbps	
Compressed music (MP3)	MP3, WMA, Ogg		128–384 Kbps
Internet radio	MP3, Real, etc.		<192 kbps
VCR-like TV	MPEG-1		1.2 Mbps
Broadcast-quality TV	MPEG-2		2–4 Mbps
Studio-quality TV	MPG-2, ITU-R 601	166 Mbps	3–8 Mbps
HDTV	MPEG-2, MPEG-4	Several Gbps	10–54 Mbps
Videoconference (H.xxx)	H.261, MPEG, Px64	64–1,536 Kbps	100 Kbps
Telepresence	Various	Several Gbps	100s of Mbps

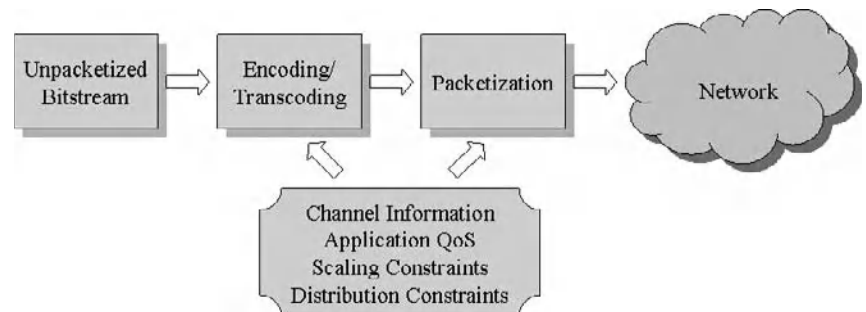

Figure 4: Media packetization process

the packetization process. Accordingly, IP packet boundaries align with video frame or audio sample boundaries rather than extending one video frame across two packets, which simplifies media-unit processing. Figure 4 depicts the simple steps in casting video and audio streams into packets, incorporation application-level information in the packetization process. The raw bitstream is encoded and packetized according to application, channel, and distribution constraints.

Media Distribution

Given the volume of multimedia content, it is paramount to use distribution methods that cause the least amount of traffic. Distributing content to clients is based either on unicast, network-native multicast, overlay multicast, also known as application-level multicast (Milic et al. 2005). With *unicast*, a separate copy of the media stream is sent from a server to each client. Broadcasting content to many receivers with repeat unicast hence causes massive data duplication. In contrast, *network multicast* sends only one copy of the media stream along the path between any two network routers, which multiplex the stream on all outgoing interfaces leading to stream subscribers. This paradigm uses network capacity

more effectively, but is more complex to deploy, because routers at the network core must all be multicast-enabled and cooperate on stream forwarding. Multicast, as 1-to- k distribution, $k \leq n$, where n is the entire receiver set, is the most general case of content distribution. With one receiver ($k = 1$) it becomes unicast, and with $k = n$ distribution it is equivalent to broadcast. *Anycast* is a special case, in which an especially qualified host from the set of k receivers is chosen, for example the fastest or least-loaded server, or the nearest cache. *Overlay multicast* is an edge-centric approach, where a network of servers instead routers perform stream forwarding, however, this paradigm incurs extra deployment cost, greater management overhead and application-level processing penalties. Although IP multicast as a rendition of network multicast lends itself to efficient and scalable distribution of live content to many receivers, current applications rather rely on repeat unicast of separate, identical streams due to multicast infrastructure deployment issues (Diot et al. 2000). Although IP multicast nowadays is available in routers of most networking vendors, it is often either deactivated or, across the mainstream Internet, blocked by firewalls. Universities and organizations running their own networks often use multicast for bandwidth-saving distribution of high-volume

data and media and for research into more effective distribution methods. A significant portion of early research work on IP multicast and distributed multimedia applications was conducted in the multicast backbone (MBone) testbed (Kumar 1996; McCanne et al. 1997).

Accelerated media delivery to end users is the primary goal of *content delivery networks* (CDN) (Saroiu et al. 2002). The core idea is to bring content closer to the user by replicating it from an origin server into an overlay network of CDN nodes in multiple locations and over multiple backbones, and using application knowledge in *content routing* to match up media sources and clients. CDN nodes cooperate with each other transparently to shift content to locations with strong user demand and thus help to offload origin servers, reduce bandwidth costs, and give end users an optimized streaming or download experience. The choice of nodes is a function of latency, the number of hops, and the cost to serve content from a specific location. An interesting alternative to established content delivery mechanisms is BitTorrent (2006), an open-source, peer-based file distribution method and protocol often used for scalable media download, which fragments a file into smaller chunks of a few hundred KB to several MB. The BitTorrent protocol matches up peers requesting content, which download missing fragments from each other and reassemble them at reception into the entire file. BitTorrent achieves better throughput and robustness than monolithic downloads in sharing large media files due to its highly distributed operation and sharing of smaller chunks of files.

Media Scaling

Audio and video transport requires computers to have sufficient processing power and bandwidth to support the required data rates, and low-latency interrupt paths in the OS kernel to prevent buffer under-run in clients. Content has hence to be adapted (Rejaie et al. 1999) according to receiver capabilities and the desired Quality of Service to scale media delivery to millions of heterogeneous receivers. Video can for example be scaled by reducing the number of bits per pixel, by reducing the display resolution, or by removing redundancy in image sequences. A cell phone user has different requirements and expectations for media delivery than a high-end desktop user. Through scaling of media, servers can hence adjust to different quality levels for media depending on fluctuating network conditions and end-host capabilities. Compression and layered encoding help servers to adapt streaming to the available bandwidth. The best quality level may be chosen with user input before streaming starts, or it may be negotiated before inception of delivery and automatically renegotiated and adjusted during delivery. Numerous solutions for media scaling have been proposed, such as layered coding or multiple description coding (Chakareski et al. 2003). *Layered coding* is based on the idea that a single sender transmits content in several layers of quality that progressively build on each other, where receivers join delivery channels according to their capabilities, receiving content asynchronously and at the quality they can handle. In *multiple description coding*, redundancy is added to data, which are broken into several streams. More bandwidth

is consumed transmitting these redundant streams, but distorted streams can be reassembled under graceful degradation, which surpasses solutions based solely on compression.

Media Synchronization

Multimedia synchronization (Steinmetz 1991) is the ordering of messages in one-way or interactive media exchange by maintaining proper timing (or spatial) relationships in content presentation, from a single or multiple sources to a single or multiple destinations. Distributed applications using multimedia data depend on synchronization to assure temporal order of events at capture, transmission, mixing, and presentation, which may also affect their coordinated access to shared resources. Multipoint synchronization comprises both the definition and establishment of temporal relationships among distributed media such as video, voice, and graphics and fundamentally affects the Quality of Service, by which end-users perceive an application service. These relationships can exist within one media stream for intra-stream synchronization, or across several streams for inter-stream synchronization. Synchronization can target a single object in one stream needing to be synchronized with an object in another stream at one point in time, or handle stream synchronization continuously over a period of time. Timing information must be transmitted along with streams, either

- before the start of the presentation, which may cause a presentation delay,
- via a separate synchronization channel, where additional errors can occur, or
- by using multiplexed data streams, where cross-related synchronization information is delivered with media units, which is difficult to use for multiple sources.

The actual synchronization operation may be performed at the source, in routers along the path, or at the receiver, which consumes more bandwidth due to transmission of extra information. Intramedia synchronization handles the temporal relationship among the objects of one stream, whereas intermedia synchronization manages the temporal relationships between the objects of two or more parallel streams. Numerous models and solutions (Escobar et al. 1992) have been proposed for synchronization with or without external clocks, and in unicast and multicast contexts.

The synchronized multimedia integration language (SMIL, pronounced “smile”) (W3C 2006) is an application-level tool to integrate timing and synchronization information into an XML-based language for composing interactive multimedia presentations. SMIL supports the description of temporal behavior in multimedia presentations in conjunction with layout and hyperlink association.

Quality-of-Service and Traffic Shaping

The concept of Quality-of-Service (QoS) for multimedia transport has a twofold purpose: to offer measurable

quality criteria for multimedia traffic useful for fine-tuning network parameters and to give users tangible criteria for system evaluation, based on the fact that not all applications need or can claim the same performance in the networks they traverse. Thus, applications may specify certain requirements to the network to optimize the transmission and user experience. Meeting the QoS requirements of multimedia traffic is challenging in the current best-effort Internet. Network performance (Fitzek and Reisslein 2001) may be acceptable when demand does not exceed capacity but deteriorates rapidly otherwise. Numerous strategies have been suggested in the literature to add QoS on top of best-effort IP. Overprovisioning in networks for voice, video, and data traffic is a costly solution, because there is always a need for higher quality and scalability. The relevant service quality criteria are typically network performance parameters such as

- Throughput (bit rate)
- End-to-end delay
- Delay variation (jitter)
- Error rate

Throughput in applications such as streaming requires constant bit rate (CBR) transmission; however, not all networks are capable of carrying CBR traffic without noticeable loss, corruption, or delay. A private branch exchange (PBX) telephone conversation generates for example a constant bit rate equal to 64 kbps. In contrast, variable bit rate (VBR) applications are inherently bursty. *Delay* (Goyal et al. 1997) consists of the processing delay in a node, the transmission delay to place packets on the channel, the propagation delay across the channel, and the cumulative queuing delay in routers. Although the transport delay cannot be avoided due to the laws of physics, it can be shortened through caching, mirroring, and content routing. *Jitter* (Stone and Jaffey 1995), or delay variation, causes speech to quiver and video to become unsteady (Claypool and Tanner 1999), and occurs when networks cannot guarantee uniform delay for separate streams to each user as a result of traffic conditions and network imperfections. The essential method to avoid jitter is to buffer sufficiently so that delay variations can be equalized before surfacing in playout. The *error rate* represents three different types of errors: the bit error rate (BER) measuring the frequency of erroneous bits, the packet error rate (PER) measuring the frequency of lost, out-of-order, duplicated, or corrupt packets, and the packet loss rate (PLR), which specifically looks at the lost packets. Subjective measurements such as the mean opinion score (MOS) for voice quality evaluation may also be taken into account. QoS entails

- Admission control, testing if a requested QoS be met while honoring earlier QoS commitments to already accepted calls
- Traffic shaping/policing, making sure that a connection obeys its specified traffic once admitted
- Path selection via routing to satisfy a requested QoS
- Flow setup, communicating call requirements to intermediate routers to reserve necessary resources (buffers, bandwidth)

- Packet scheduling, managing the packets in the router queue to receive the requested service

QoS controls can be established from the network edge, or through the network core. The resource reservation protocol (RSVP) (Zhang et al. 1993) was a distinct approach for adding QoS to best-effort IP. “Network QoS” and “End-System QoS” discuss Quality-of-Service in more detail. Several principles to warrant service guarantees have been suggested (Kurose 2007), such as

- Packet marking to let routers distinguish between different service classes
- Policing and scheduling mechanisms to isolate one traffic class from another class and ensure efficient allocation for flows, for example, with weighted fair queuing, which sequences packets and allocates bandwidth to packet flows through various queues and weights determined by application needs and link capabilities
- Admission control to block unfitting flows

Media-Aware Congestion Control and Rate Control

The evolution to media-rich computing would not have been possible without major efforts in protocol standardization and cooperative deployment of services. Yet, although the market forces and customer interests are shifting towards media-integrated computing and networking, the existing infrastructure of the Internet was designed for non-continuous, bursty, and discrete data transfers under elastic time constraints. Despite concerted efforts in deploying helper protocols to leverage media-rich computing and networking, multimedia networking is still coming of age. This shows in particular when flash crowds and peak hours in Internet usage put heavy performance strains on a global network, where discrete data and continuous media transmissions must coexist in a fair manner. Although new technologies and trends in collaboration and communication leverage our collective abilities to work together, their bandwidth-intensive use poses a threat to the stability of the Internet, as they generally use non-congestion controlled transport protocols to satisfy timely delivery constraints. Some of the key components in network scalability are congestion avoidance and rate control for voice and video (Bolot and Vega Garcia 1996; Bolot and Turetletti 1998), which in many variations of TCP implementations walk a fine line between network reliability and performance (Rhee and Xu 2005).

Currently implemented congestion control is oblivious of the semantics of packets carried, and does not cater to the specific transport characteristics of multimedia. Improving congestion control for multicast applications is still research matter, and networked multimedia systems are prone to unpredictable performance and low-grade quality both in delay and presentation as a result of a lack of sufficient capacity provisioning, and the fact that the underlying networking protocols have been designed primarily for a media-impooverished computing environment. Both unicast and multicast congestion control build

on the notion of TCP fairness and friendliness to permit continuous and non-continuous media to coexist with reasonable allocation of bandwidth in the face of Quality-of-Service demands. Media-aware congestion control provides the backend support for interactive media flows, complementing TCP-friendly rate adaptation mechanisms in their support of one-directional streaming applications. In addition, continuous-media protocols should not use more than their “fair share” of network bandwidth. A flow is TCP-fair if its average rate matches what the average TCP rate would be on the same path, and TCP-friendly if its average rate is less than or equal to the TCP-fair rate. This results in the same transmission rate as TCP along the same data path, but with less rate variance, and hence, less oscillation, catering to the continuous playout requirement of media streams. Media awareness has the objective to make media-heavy applications operating under non-ideal network behavior more robust and effective.

NETWORK MIDDLEWARE AND PROTOCOLS

Multimedia Protocol Stack

The various protocols augmenting the Internet protocol stack to transport multimedia (Braun 1997) are shown in Figure 5. This suite of multimedia protocols adds middleware functionality to the Internet protocol stack to extend its best-effort service to time-aware, continuous media transport using the real-time transport protocol (RTP) and its helper protocols, RTSP and RTCP. Top-level protocols, for example HTTP or peer-to-peer protocols such as BitTorrent, feed their parameters into helper protocols mediating between applications and the transport layer. These protocols perform media transport with QoS (Aurrecoechea et al. 1998), using either TCP or UDP as transport service. At the bottom of the multimedia stack are link layer and physical services such as SONET, ATM, or Ethernet in local networks. The ATM adaptation layer (AAL) protocol or the point-to-point protocol provide the glue between network and physical layer services (Leon-Garcia 2001.)

Signaling and Session Control Protocols

The ITU-T H.323 standard is an umbrella recommendation for audio-visual communication services over packet networks, and is often used for voice over IP (VoIP) applications, IP telephony, and video conferencing. At the heart of the H.323 architecture is a gateway connecting the telephone network to the Internet, and a gatekeeper controlling the end points in its zone. H.323 adopted RTP as the first VoIP protocol for audio and video transport. Several protocols belong to the H.323 standard:

- The G.7xx protocol suite for speech encoding and decoding
- The real-time transport control protocol (RTCP) to control RTP channels
- The H.225 (RAS) registration/admission status protocol to manage the PC-gatekeeper channel
- The ITU Q.931 signaling protocol to establish and release connections, and to provide traditional phone functions such as the dial-tone
- The H.245 call control protocol for negotiating compression and bit rate of the link, and
- The RTP protocol for the actual data transport

During a H.323 session, five channels are accordingly open between caller and callee, dedicated to signaling, call control, upstream and downstream data channels, and a data control channel.

In response to the telco-steered H.323 standard, which was perceived as complex and inflexible, the Internet Engineering Task Force set off to create a simpler, lightweight and modular mechanism for VoIP. The Session Initiation Protocol (SIP) (RFC 2543, 3261) has been developed by the IETF MMUSIC working group to manage interactive sessions using multimedia, as with instant messaging, online gaming and, in particular, Internet phone applications. SIP is a text-based protocol modeled after HTTP, and clients use TCP and UDP port 5060 to connect to SIP servers to set up and tear down voice or video calls. The actual voice or video communication is handled over RTP. SIP components include the UAC (user agent client), the

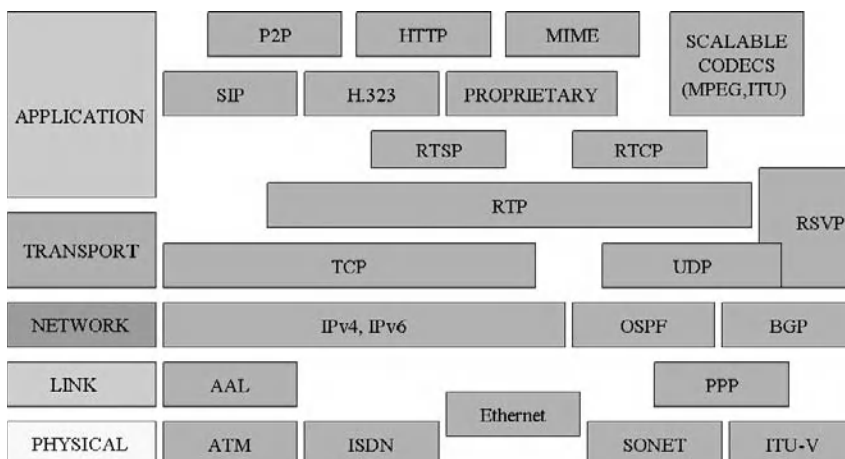

Figure 5: Internet multimedia protocol stack

UAS (user agent server), a SIP terminal, a proxy, a redirect server, and a location server. A connection is established, when a caller sends via TCP an INVITE message to the callee located with the help of a location server. The callee responds with a HTTP-type reply code to accept or deny the invitation. SIP is largely compatible with PSTN and modular, opposite to the monolithic protocol stack prescribed by H.323. SIP uses URLs for addressing, whereas H.323 uses host or telephone numbers.

SIP is only involved in the signaling portion of a communication session and acts as a carrier for the Session Description Protocol (SDP), which describes the media content of the session, such as the IP ports or codec being used. SDP (RFC 2327) provides short structured textual description of the name, port, and purpose of a session, the pertinent media, protocols, codec formats, timing and transport information required to decide whether a session is likely to be of interest and to know how to start media tools to participate in the session. SDP provides merely a format for session description and does not depend on a specific transport protocol.

The RTCP (Real-time Control Protocol), as a companion watchdog protocol for RTP, provides feedback on the reception quality of the distribution and helps to fine-tune RTP QoS. It delivers reports on receiver reception, sender performance and a source description to modify sender transmission rates and for diagnostics purposes. RTCP is a soft-state, announce-listen protocol, whose report frequency is adjusted to minimize network impact by limiting its traffic to 5 percent of a session bandwidth. The Real-Time Streaming Protocol (RTSP, RFC 2326) is an open-source application-layer protocol that allows the user to control a media bit stream in VCR-style remote control directly through a media player. The main protocol vocabulary of RTSP consists of directives to describe stream parameters, set up a logical control channel between a player and server, play, record, and pause streams, and tear down the connection at completion or user interrupt. Playback control, the choice between different quality levels, authentication and clip information are all conveyed via RTSP, which has been used for Quicktime, Realplayer, and Windows Media Player. RTSP may use RTP as underlying transport protocol for the actual transfer of audio and video information, or a proprietary transport mechanism such as the RealNetworks' RDT protocol (RealNetworks 2007). Besides RTSP, other streaming protocols such as Microsoft's Media Server Protocol (MMS) and RealNetworks' progressive networks audio (PNA) protocol have been proposed (Kuenkel 2003). Popular media players relieve the user from choosing a transport protocol and automatically attempt transmission first via RTSP/MMS and UDP, then RTSP/MMS and TCP, and, if streaming protocols are blocked, via HTTP as a last resort.

Quality-of-Service Protocols

Among the control protocols used to ensure QoS (Shenker 1995; Campbell et al. 1996) in media transmission, the RSVP (Resource Reservation Protocol) was designed for an integrated services (IntServ) approach (Clark et al. 1992) to request a specific QoS from the network on behalf of

an application data stream. RSVP is receiver-initiated, handles unicast and multicast flows, and is decoupled from routing. As the routing changes, RSVP adapts its reservation to the new paths wherever reservations are in place. RSVP runs over IPv4 and IPv6 and provides opaque transport of traffic control and policy control messages. An RSVP request is carried from an end-host through the network, visiting each node that the network uses to carry the stream. At each node, RSVP attempts to make a resource reservation for the stream with RSVP daemon communicating with two local decision modules, admission control, and policy control. RSVP requires routers to carry a lot of state and is difficult to manage as a result of the potentially large number of flows.

The alternative differentiated services (DiffServ) approach (RFC 2638) provides simple functions in the network core and more complex functions at edge routers hosts, and does not define service classes, but rather enables router to distinguish traffic classes and queued packets accordingly through packet markers. As another alternative, Multi-Protocol Label Switching (MPLS) (RFC 3031) has been proposed to integrate QoS provision into routing. MPLS emulates properties of a circuit-switched network over a packet-switched network. MPLS labeled packets are switched according to a label lookup reflecting QoS choices instead of a routing table lookup, which can be done directly in the router fabric and not the CPU.

Media Transport Protocols

Real-time flows on the Internet are largely handled by the Real-time Transport Protocol (RTP) (Schulzrinne and Rosenberg 1999; RFC 1889). Other transport protocols such as XTP or the Tenet (Banerjee et al. 1996) protocol suite have been proposed before the introduction of RTP, which is a middleware protocol on top of end-to-end protocols such as UDP, TCP, or ST-II. It provides a standard packet header with media-specific timestamp information, payload specifics, and sequence numbers to transport packet flows for continuous media, carrying information for playout synchronization, demultiplexing of multimedia flows, quality-of-service monitoring, and media identification that other transport services would not specifically carry. Commonly, RTP flows are connectionless and packets are carried by UDP, which does not warrant against packet loss or corruption. Although RTP carries timing information, maintaining real-time constraints is not guaranteed with using RTP. Successful RTP media flows depend on sufficient capacity in the underlying traffic class, whose provision is a separate concern. The RTP header is 8 octets long and contains fields for the protocol version, a flow identifier, an options bit, a synchronization bit, a content type index, a packet sequence number, and a timestamp. More information on RTP is provided in "Multimedia Streaming".

IP MEDIA

Voice and Video over IP are sometimes subsumed under IP media, which includes all on-demand, streaming and subscriber-based content available over broadband Internet.

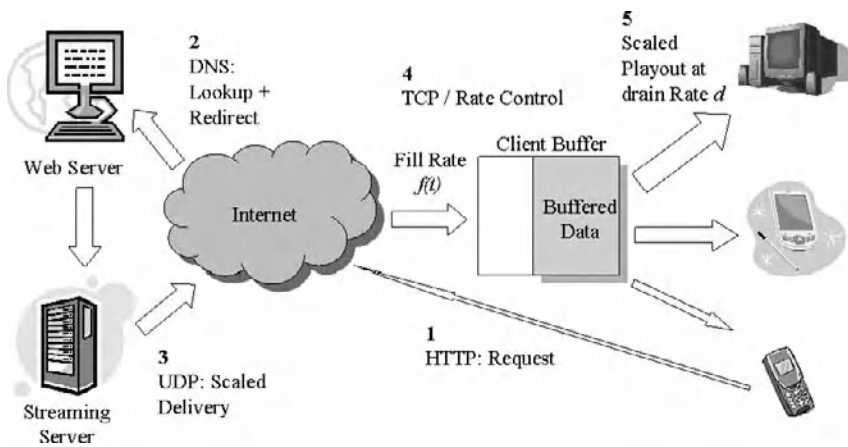

Figure 6: Streaming with media scaling

Streaming Protocols and Platforms

Before computer networks and end-hosts had the necessary capacity, multimedia were primarily distributed via non-streamed media such as CD-ROMs. Although traditional media delivery such as radio or television is inherently based on streamed delivery of content, the term streaming is now typically used for a distribution mechanism across computer networks, where media packets are being consumed during continuous delivery. Streaming (Wu et al. 2001) bypasses the need to download the entire file before playback and caters to limited storage and bandwidth capabilities of devices.

A typical streaming setup involves an audio or video source, a server or stream reflector, and a client where the stream is being played back. Figure 6 shows a setup with a cell phone, PDA, or desktop computer as clients, running a media player with a playout buffer; a Web server; and/or a streaming server. The content must be delivered in a coding format that the server has available and the client can understand. The media player manages the user interface, decompresses the incoming audio, handles transmission errors, and eliminates jitter through buffering.

First, one of these devices establishes a TCP connection and HTTP request from a browser or media player (both may be integrated) to a Web server orchestrating access to a media collection. The server might retrieve the media file locally or, through the domain name system, resolve to a streaming server, which retrieves a window of the requested media stream at a certain size or quality from its disk and responds to the client. Once the client knows the address of the streaming server, it will talk to the server directly. The streaming server may detect the capabilities of the client via protocol header information or by first testing the connection to the client, and scale its media stream accordingly to avoid that the client waits too long or receives a stream beyond its output capabilities. The stream data may also be cached along the path so that future requests can be satisfied more quickly. The media player in the client will start playout of the stream from the playout buffer once a sufficient amount of data is held in it. The client buffer is filled at rate $f(t)$ and emptied at rate d . Ideally, $f(t) = d$, that is, the server will fill the buffer at exactly the same rate it is being drained by the player.

If the drain rate exceeds the fill rate, the buffer may under-run. If the media stream fills the buffer faster than the drain rate and beyond capacity, packets may get lost due to buffer overrun. In either case, a *gap problem* occurs, where video stops at the last available frame, or the audio stream stops in mid-play. By setting an upper and lower threshold, the server and client can communicate about throttling of the stream to calibrate toward the optimal speed.

Widespread deployment of media streaming hence raises scaling, Quality-of-Service, and service testing issues. For efficiency reasons, streaming is typically implemented on top of UDP, using RTP and companion protocols. It is possible to use HTTP for streaming with the benefit that HTTP flows easily pass through firewalls, however, as an application layer protocol designed for fast retrieval of static web objects it does not offer direct control of the bit stream. Furthermore, HTTP runs on top of TCP, which guarantees bit-wise correct delivery, however, timeouts and retransmissions for reliability make streaming via TCP more complex and slow. UDP on the other hand sends the media stream as a series of datagrams, but packets can be lost or corrupted in transit. Depending on the extent of the loss, the client may be able to recover the data with error correction techniques, may interpolate over the missing data, or may suffer a dropout. Firewalls are more likely to block UDP-based protocols.

Single stream servers are sooner or later overloaded and their operation is constrained by the available bandwidth, system availability and resources (storage, memory, CPU), and limitations in system software. Media streams may stall while the protocol handler detect data loss and retransmits the missing data, which necessitates more look-ahead buffering in clients defeating the intention of streamed content. In order to offload a single source server, media are often distributed in a server farm, or via splitters to other servers. Load balancing between servers is needed to assign encoding, splitting and serving to servers according to load and link usage, with the goal to maximize availability and response time. Splitting has two variants; in *pull splitting* an origin server contacts a splitter only for content replication when a client request the content from the splitter, which saves bandwidth for

small audiences. In *push splitting*, a server by default forwards a freshly encoded stream to connected splitters for distribution.

Commercial Internet audio streaming was first introduced by RealNetworks in 1995 and expanded in 1997 to include video streaming with proprietary codecs, using the RTP and RTSP protocols. Today, numerous open-source and proprietary streaming solutions, including RealPlayer (RealNetworks 2007), iTunes with Quicktime (Apple 2007), and the Windows Media Player (Microsoft 2007) offer alternatives for end users to playback content from dedicated media servers or Web servers in various formats. Empirical studies with RealAudio traffic (Mena and Heidemann 2000) have shown that audio traffic is different from regular FTP, HTTP, or Telnet traffic. Audio sessions have longer duration, while user arrivals correlate with the time of day similar to regular web traffic. In addition, UDP audio flows, which can be identified by packet length and packet inter-departure time, are mostly unidirectional from the server. Similar studies have been conducted for RealVideo traffic (Wang et al. 2001).

Innovative streaming models are based on a peer-to-peer (P2P) architecture (Deshpande et al. 2001; Freecast et al. 2006), which links clients directly up for one-on-one media exchange. P2P streaming offloads dedicated media servers and the network, but raises other technical, business, and legal issues. Availability of streaming peers cannot always be guaranteed, users cannot be prevented from recording streamed content, and content distributors may use proprietary formats and encryption or rely on copyrights, patents, and license agreements to make local archival more difficult. It remains to be seen whether P2P video transport such as Joost (2007) will make its mark as Skype (Baset and Schulzrinne 2004) did for VoIP. "Multimedia Streaming" contains further details on video streaming.

Voice over IP

Voice over IP (VoIP) digitizes and packetizes voice (Bolot and Vega Garcia 1996) into discrete units sent across the Internet, rather than using legacy circuit-based mechanisms of the public switched telephone network (PSTN). Recent advances in such Internet telephony threaten to erode the market for legacy telecommunication services. A voice agent at the edge of the network converts information from a regular telephone into packets for Internet transmission, which may be subject to various levels of degradation at playout (Watson and Sasse 2000). The main issues in VoIP revolve around voice coding, signaling between parties, addressing between a PBX and IP host, port configuration, and error recovery (Boutremans et al. 2002). The latter is typically handled with retransmission, when possible, adding redundancy, interleaving of audio packets can be used to make streaming more robust against burst errors, so that a media layer can interpolate between missing samples, or with forward error correction. Advances in VoIP are steered by the VoIP Forum, a coalition of major networking vendors to promote the use of ITU-T H.323 as the standard for sending voice and video over IP across the public Internet and within intranets. VoIP protocols generally use RTP to ensure timely delivery of packets on top of best-effort

Internet services. Directory services, emergency calling, and the use of touch-tone signals for automatic call distribution and voice mail are component services within VoIP. Typically, an organization places a VoIP box at a gateway, which receives packetized voice transmissions from users and routes them to other parts of an intranet or, using a T-carrier system or E-carrier interface, sends them over the public switched telephone network. Various open and proprietary solutions to improve call quality have been part of the VoIP evolution, for example the technique to ping all possible network gateway computers with access to the public network and choosing the fastest path before establishing a socket connection between end points. VoIP implementations use open standards such as SIP or H.323, or proprietary protocols (Baset and Schulzrinne 2004). VoIP is often synonymous with Internet telephony (Schulzrinne and Rosenberg 1999). For more information on Voice-over-IP and packet-based audio, see "Voice over IP (VoIP)".

Video over IP

Packet video (Bolot and Turletti 1998) finds its main incarnation in Internet TV, Web TV, and Webcasts, using Internet broadband connections or Web portals for digital broadcast. Typically Internet TV is based on Web-centric streaming of content. With improvements in broadband, the rising Internet user base, and decrease in connection cost, it is expected that video over IP will be a dominating market and new revenue opportunity for telecommunications providers, promising lower costs for operators and lower prices for consumers.

APPLICATIONS OF MULTIMEDIA NETWORKING

Applications for networked multimedia are manifold—examples are video-on-demand and multimedia-aided home shopping for residential services, video conferencing, and corporate training in business, distance education and use of digital libraries in education, distributed computation and collaborative data mining in the sciences, or distributed diagnosis and treatment in medicine. Networked multimedia applications, opposite to data-centric applications, stand out due to their delay sensitivity and loss tolerance. A media stream that arrives a few hundred milliseconds later at the receiver than an audio stream becomes useless, but a few lost packets in a stream will not harm the playout of a video stream significantly and can often be concealed.

Classes of Multimedia Applications

Multimedia applications can be differentiated according to the nature of the media (on demand, live, or interactive) (Kurose 2004), the type of devices (fixed or mobile), and the location and time of source and receiver (same or different time, same or different place.) On demand streams are stored on a server for a longer period of time, and are available to be transmitted at a user's request.

Table 4: Networked Multimedia Application Types

	Stored	Live	Interactive
Unicast (Point-to-point)	Multimedia Mail Media Blogs	P2P Streaming	Internet Telephony Collaboration
Multicast (One-to-many)	Video on Demand Media Syndication	Internet Radio Internet TV	Conferencing Telepresence

Live streams are only available at one particular time, as in a video stream of a live sporting event.

Table 4 categorizes various applications according to their distribution mode and freshness. One-to-many delivery may use network or end-system multicast. In particular,

- *Media on demand* delivers *stored* audio or video to end users, for example through video on demand
- *Live media* streaming brings real-time content to users, for example with Internet radio
- *Interactive media* deliver real-time audio or video, for example in IP telephony or video conferencing

The simplest type involves attachment of multimedia objects to regular data traffic such as MIME e-mail or weblogs. Video on demand or content syndication such as RSS may take advantage of multipoint delivery. Peer-based streaming applications are typically also point-to-point, and live. Live streaming applications such Internet radio broadcast or TV may benefit from multicast distribution. Interactive unicast or multicast cases are represented by Internet phone or collaboration applications, video conferencing and tele-immersive, virtual-reality systems. Notably, media encoding and transport may be quite different depending on whether the senders and receivers are stationary or mobile.

Media on Demand

Streaming of stored audio and video entails on-demand transmission of content from media servers, where users can pause, stop, forward, and rewind the presentation using a control protocol such as RTSP as with a traditional VCR or DVD player, albeit with a greater delay due to network latency. Content playout should adhere to the timing properties of the original recording and requires that the media server delivers each media unit in time for proper playout at the client. However, as long as packets are in the buffer when needed, it does not matter when they arrive or how substantial jitter is. End-to-end delay constraints are less stringent compared to live-casts or interactive applications such as teleconferencing. Video on demand (VoD) of archived material represents this class. In Internet-based VoD, users can watch selective video content accessible from a Web site or application as part of an interactive television system. VoD systems may stream or download content, the latter storing a program in its entirety into a set-top box or the PC hard disk

before viewing starts. A solution for greater scalability is Near Video On Demand (NVoD), where replicas of the same program are transmitted in regular time intervals, for example every 20 minutes, to aggregate streams and save bandwidth over individual on-demand broadcasts, while giving consumers some time flexibility to tune into a specific program. YouTube (2007) and similar video sharing services enable users to broadcast video materials on-the-fly and mark the transition into a new age of instant sharing of personal and dynamic multimedia content.

Live Media

Streaming of live audio and video resembles traditional broadcast, in which content is fed live into the Internet and distributed via reflector servers to various receivers around the globe. Opposite to media on demand delivery, which is typically point-to-point, live streaming targets large audiences. Live streams require also continuous play-out where users can tolerate delays in tens of seconds. The live nature of content prohibits immediate stream control, although it is possible to couple such content playout with a digital video recorder (DVR) to allow later viewing and VCR-like manipulation.

Since its inception in 1995 with Internet Talk Radio on the Mbone, streaming radio transmits live or stored content from a traditional radio station or an Internet radio station. Opposite to terrestrial radio, content can hence be created and accessed through the Internet anywhere, similar to the spirit of satellite radio. Instead of tuning into a traditional radio station, a Web search is used to find stations and streams of interest. Content is captured through an audio plugin, encoded in a media player, pushed on the Internet and stored or forwarded through a media server, which distributes it to a large number of TCP connections. Internet radio seems predestined for multicast, but TCP unicast is often used for radio flows, because RTP is blocked, whereas TCP is allowed through firewalls, and multicast is generally not available through ISPs. There is a trade-off between audience size and audio quality. Bandwidth is used more economically when more users with low grade connections can listen to stations transmitting at lower quality. At near CD quality, one T1 line can only handle under ten streams at 192 kbps. Hence streaming radio is often blocked in corporate settings to avoid bandwidth depletion. Podcasting is an asynchronous spin-off from Internet radio, where audio and video content similar to radio and TV content is published in various ways,

including RSS feeds and peer-to-peer platforms. In contrast to Internet radio, pod casting is more a collaboration and sharing platform and allows media viewing independent of broadcast time.

Internet television is sometimes shortened to IPTV and may show exclusive content only found on the Internet, or content simulcast online and via traditional TV. It offers an alternative to legacy distribution via cable, terrestrial and satellite broadcast and is often coupled with video on demand. In contrast to traditional broadcast, IPTV allows for two-way, interactive transmissions and selective point-to-point transmission. Innovations such as the SlingBox (Sling Media 2007) allow forwarding home-subscribed TV to laptops on the road and bridge both worlds; PVRs complement these services and allow selective, simultaneous recording of multiple programs on home computers or specialized appliances; and existing pay-TV channels can be transmitted over the Internet to regular TV sets. As of January 2007, several thousand IPTV channels are available either free or fee-based. Online channels require only a broadband connection and a video-capable device, such as a set-top-box, PC, or HDTV, or a handheld such as an iPod or 3G cell phone for mobile TV. Video content comes in various formats such as MPEG-2 transport streams, DivX, MPEG-4, or H.264. IPTV has previously been implemented using the Internet group management protocol (IGMP) version 2 for live TV and RTSP for video on demand. The major bottlenecks for scalable, high-quality video distribution have been open and free encoding methods, streaming protocols, and available bandwidth to households. Similar to the peer-to-peer method used in Skype for Internet telephony, movie downloads via the Internet and Internet television (Joost 2007) are now available to the greater Internet community. Such highly scalable “disruptive” (Oram 2001) applications promise to revolutionize the way our global society is producing, sharing, and consuming digital media. In the long run these innovations will fundamentally change the media broadcast infrastructure. See “Peer-to-Peer Network Architecture” and “Peer-to-Peer Network Applications” for details on peer-to-peer systems.

Interactive Media and the World Wide Web

Interactive real-time audio and video (Nouredine and Tobagi 2002) imposes the most stringent delay constraints in the order of a few hundred milliseconds, because users interact with each other directly. In contrast to legacy circuit-switched interaction, call directories, larger-scale group communication, and integration with calendar and Web applications enhance the spectrum of available services through the Internet. This class of services is mostly represented by Internet phone applications, instant messaging tools, and conferencing applications (Turletti and Huitema 1996). Voice delay should be less than 150 ms to be unnoticeable to the listener, and must be less than 400 ms to yield acceptable conversation quality.

Pervasive audio and video, through wireless networks and nomadic devices, is destined to become a cornerstone in emerging communication services, and requires novel integrative approaches of signal processing and

networking technology. Generally, these services are hidden from the user and concern low-bit rate, scalable, and multiple description encoding methods, error concealment and resilience measures, transcoding for interoperability across heterogeneous channels and platforms, quality measurements for mobile media distribution, as well as novel ways for user subscription and participation.

Currently the predominant interactive application is Internet telephony, where both server-based and peer-to-peer solutions compete for users. Video conferencing (see “Video Conferencing”) and chat tools sometimes complement an Internet phone application, augmenting the instant exchange experience with text and personal presence. Voice-over-broadband companies such as Vonage (2006) require that customers acquire a phone adapter to enable their broadband router or modem to use the proprietary VoIP service. Speech packets to and from the Internet are processed by the phone adapter or integrated “VoIP router” and enable users to connect to regular telephones. An upload speed of 30-90 Kbps and a QoS optimized connection are necessary to make calls without substantial lag or jitter.

As an alternative to client-server solutions, peer-to-peer approaches may offer better scalability and robustness (Singh and Schulzrinne 2004). The Skype application and protocol uses a proprietary peer-to-peer based approach to establish voice and video calls among subscribers across an overlay network organized by supernodes. As a result of the decentralized peer-based approach, a Skype overlay network can scale easily to millions of users without a centralized, costly infrastructure and allows to traverse hosts with symmetric Network Address Translation (NAT) and firewalls. Skype allows users to both make PC-to-PC, phone-to-PC (SkypeIn), and PC-to-phone (SkypeOut) calls, with the latter two fee-based modes requiring routing across media gateways into a POTS network. Skype supposedly (Baset and Schulzrinne 2004) uses the STUN (simple traversal of UDP over NATs) protocol (RFC 3489) to create UDP communication between two hosts behind NAT routers. STUN allows media clients and servers to interconnect across firewalls, using client-server communication to find out the public IP address of a NAT, and its port to allow incoming traffic back in to the network.

Other media-rich, interactive applications have emerged in recent years on the World Wide Web. Blogs for rapid Web content authoring have replaced Usenet services, Wikis provide a platform for collaborative document creation, content syndication is used as a meta-tool to manage Web feeds for aggregated content sharing from Web sites, Web logs, and podcasts, and social computing provides a Web-based multimedia forum to deepen personal relations. Multimedia messaging via cell phones is based on the Synchronized Multimedia Integration Language (SMIL) as a recommendation by the World Wide Web Forum (W3C 2006) for describing multimedia presentations using XML (eXtensible Markup Language). SMIL is used in mobile communication for Multimedia Messaging Services (MMS) as an multimedia-rich version of Short Message Service (SMS), providing timing markup, media embedding and transitions, and media layout for Web content. Telepresence and collaboration through computer networks are the ultimate realization of networked,

interactive workspaces, providing media-rich immersion in a mixture of real-world and virtual worlds.

CONCLUSION

Multimedia networking has become a pervasive and indispensable part of everyday personal and business interactions. Video conferencing, audio and video streaming, Internet telephony, media-rich Web content and mobile multimedia sharing through pod-casting and cell phones are now part of everyday interactions and the past few decades mark a shift from the age of discrete data processing to a new era of continuous media. The Internet-enabled home theater, Wi-Fi enabled pocket media players, media extenders forwarding video and audio streams from the PC to a traditional TV or stereo, cell phones with Internet TV capability, or Internet phone software for handhelds exemplify the wide spectrum of recent innovations in network-enabled multimedia consumer products.

This chapter discussed the principles of multimedia transmission through networks. Although the best-effort Internet is ill-prepared to transport time-critical media flows to the satisfaction of the millions of music, movie, and gaming consumers, numerous solutions have been proposed and implemented to fulfill these higher expectations. Protocols for multicasting, streaming, caching and content distribution, synchronization, real-time transport and control, and Quality-of-Service have been added to the Internet services repertoire to cater to the time-critical, loss-tolerant nature of multimedia distribution. Some of these services may change or completely disappear with the impending shift to IPv6.

What will the future hold for multimedia communications? With predicted increases in broadband capacity and user base, the near future promises greater diversity in services, in terms of interactivity and customized responses to user demands, mobility, immediacy and the quality in how users can create, access, and share multimedia content through networks. In particular, these advances entail improved representation and semantic metadata analysis of media, ubiquitous “anytime, anywhere” access to multimedia content, easy-to-use interfaces for all types of users, robust and safe connection together with diversified billing, seamless connectivity and interoperability between devices and encoding formats, user-tailored presentation, greater authoring and immediate sharing options for multimedia content across networks, linkage between TV-style appliances and the Web with near zero-delay availability of content (Paris et al. 1999), and, along with the evolution of high-speed networking, tele-immersive media use in everyday life with a greater sense of reality due to increased distribution quality. Social networking is also greatly boosted through the integrated use of multimedia applications.

Such services require technical progress in search and compression algorithms, metadata processing, media security, user interfaces and media handling, intelligent agents, media conversion, content production, multimedia service composition, and last but not least, network middleware. Service composition allows more efficient provisioning and improved reusability of components in the shift from data-driven to service-driven architectures,

and from monolithic multimedia applications towards more flexible solutions, merging novel Web-based service oriented concepts and more sophisticated handling and processing of multimedia data. Continuous media carry an expressive power unmatched by words or static images. Multimedia networks enable new modalities of how people share information and express themselves, and their technical evolution will continue to have profound ripple effects on the social fabric, business, and governance.

GLOSSARY

ABR: Allocation of available bandwidth fairly according to resource consumption (primarily in ATM).

Admission control: Mechanism to control which traffic should be admitted to a network link.

ALF (Application-level framing): Protocol design principle stating that networking mechanisms such as packetization should be coordinated with application-level objectives.

ATM (Asynchronous Transfer Mode): Circuit-switching technology for telecommunications via computer networks.

Bursty traffic: Oscillating network traffic volume.

Codec: Coder-Decoder device or program for encoding and decoding of a signal or data stream.

DVP (Digital Video broadcast Protocol): Multimedia home platform (DVB-MHP) supporting the development of consumer video system applications under open standards for digital television.

E-carrier: European digital transmission format devised by the ITU-TS, equivalent of the North American T-carrier system, carrying data at a rate of 2.048 million bits per second with 32 channels of 64 Kbps each.

Gap problem: Lack of packets in audio or video stream leading to a visible or audible gap during playout.

H.263: Low-bit rate video codec by the ITU-T, designed for videoconferencing as replacement for H.261.

H.264: Advanced video coding standard (MPEG-4 Part 10) with very high data compression created by the ITU-T Video Coding Experts Group for videoconferencing and multimedia telephony.

ISDN (Integrated Services Digital Network): Circuit-switched telephone network system designed for digital transmission of voice and data over ordinary telephone copper wires with better quality than analog communication.

Jitter: Variability of packet delays within the same packet stream.

Lip synchronization: Method to keep audio and video frames in synchrony during playback.

MBone (Multicast Backbone): Dedicated testbed to deploy and evaluate IP multicast.

Media gateway: Translation unit between telecommunications networks (PSTN, 2G, 2.5G, 3G, PBX, NGN) to enable multimedia communication over multiple transport protocols.

MIME: (Multipurpose Internet Mail Extension) Extension of the Internet mail message format to carry non-US-ASCII textual messages, non-US-ASCII information, non-textual messages, and multipart message bodies.

MMS (Multimedia Message Service): Short message service for mobile devices with similarities to SMS, but with support for picture, audio, and video attachments.

Multicast: Allows sending just one message to reach a variable group of receivers through routers or servers replicating the message along the path to destinations at critical junctures leading to the receivers. It is more efficient and scalable than unicast to handle large messages and streams and hence particularly well-suited for multimedia transport.

Multimedia content: Various types and forms of multimedia information such as text, graphics, HTML, XML, dynamic Web pages, images, animations, sound or video, and files. Content differs not only in its semantics but also in how it is organized, delivered, and presented.

NGN (Next Generation Network): Packet-based network able to provide services including Telecommunication Services and able to make use of multiple broadband, Quality-of-Service-(QoS) enabled transport technologies and in which service-related functions are independent from underlying transport-related technologies.

NVP (Network Voice Protocol): Ancestor protocol of modern day VoIP technology (RFC 741).

Nyquist theorem (aka sampling theorem): States that discrete samples of a signal are a complete representation if the bandwidth is less than half the sampling rate, which is referred to as the Nyquist frequency.

PBX (Private Branch eXchange): Private telephone network used within an enterprise, sharing a certain number of outside lines for making telephone calls external to the PBX.

Policy: Rule assigned to a specific traffic class to determine how a single packet flow will be handled during bandwidth allocation.

QoS (Quality-of-Service): Measure of the performance of a network component against expectations. QoS parameters include jitter, skew, bandwidth, loss rate, and error rate.

Rate control: TCP-specific method to throttle traffic flow according to sender and receiver capabilities and in balance with other concurrent traffic flows.

RSVP (Resource Reservation Protocol): Reservation-based protocol to control receiver-initiated allocation of resources in an integrated services Internet for multicast or unicast data flows.

RTCP (Real-time Control Transport Protocol): Out-of-band watchdog protocol for RTP flows (RFC 3550).

RTP (Real-time Transport Protocol): Transmission protocol for audio and video over the Internet (RFC 1889).

RTSP (Real-time Streaming Protocol): Control protocol for time-based access to files on a streaming media server using VCR-like commands (RFC 2326).

SIP (Session Invitation Protocol): Control protocol to conduct interactive user sessions using multimedia data, often used for voice over IP along with H.323.

ST-II (Streaming Protocol version 2): IP-layer protocol to provide end-to-end service guarantees across the Internet (RFC 1190).

Streaming: Delivery of multimedia data without complete download and with playout during the delivery process.

T-carrier: Entirely digital North American carrier system introduced in 1960 using pulse code modulation (PCM) and time-division multiplexing (TDM) to support digitized voice transmission, with an original transmission rate of 1.544 Mbps for a T1 digital stream consisting of 24 64-Kbps multiplexed channels.

Traffic shaping: Bandwidth management directive to improve default bandwidth allocation by enforcing policies on traffic flows and aggregate flow partitions in a traffic class.

Near-VoD: Bandwidth-saving version of video on demand where video stream transmission is staggered and a new stream of the same content is transmitted at regular, announced time intervals for viewing of video content through networks.

VoIP (Voice over IP): IP telephony term for delivery services to carry voice information over the Internet, avoiding toll charges by ordinary telephone services.

INTRODUCTION

This chapter provides a basic introduction to the Internet and various Web technologies. It provides a brief history of the Internet and then explains domain name systems, navigational tools, and search engines. The chapter defines intranets and extranets and compares and contrasts them with the Internet. The chapter concludes with a brief survey of popular applications of the Internet in various industries and fields, including tourism and travel, publishing, higher education, real estate, employment, banking and brokerages, software distribution, healthcare, and politics. Other chapters throughout the *Handbook* discuss in more detail most of the topics presented here.

INFORMATION SUPERHIGHWAY AND THE WORLD WIDE WEB

The backbone of the information superhighway and electronic commerce (e-commerce) is the Internet. The Internet is a collection of millions of computers and networks of all sizes. Simply put, the Internet is the “network of networks.” The information superhighway is also known as the Internet. No one actually owns or runs the Internet. Each network is locally administered and funded, in some cases by volunteers. Most countries throughout the world are directly or indirectly connected to the Internet making global e-commerce a reality.

The Internet started in 1969 as a United States Department of Defense project called ARPANET (Advanced Research Projects Agency Network). It served from 1969 through 1990 as the basis for early networking research and as a central backbone network during the development of the Internet. Since the Internet began, it has grown rapidly in size. ARPANET evolved into the NSFNET (National Science Foundation Network) in 1987. NSFNET is considered the initial Internet backbone. The

term “Internet” was derived from the term “internetworking,” which signified the connecting of networks. The physical network was established in 1969, connecting four nodes: University of California at Los Angeles, University of California at Santa Barbara, Stanford Research Institute (at Stanford), and University of Utah at Salt Lake City. The network was wired together via 50Kbps circuits. Other nodes composed of computer networks from universities and government laboratories were subsequently added to the network. Taken together, these initial connections linked all existing networks in a three-level hierarchical structure:

- backbones
- regional networks
- local area networks (LANs)

Backbones provide connectivity to other international backbones. The NAPs (network access points) are a key component of the Internet backbones. NAP is a public network exchange facility where Internet service providers (ISPs) can connect with one another. The connections within NAPs determine how traffic is routed over the Internet and also are the focus of Internet congestion. Individual LANs became a standard connection interface through which computers could gain access to the Internet. Phone lines (twisted pair), coaxial cables, microwaves, satellites, and other communications media are used to connect LANs to regional networks. TCP/IP (transmission control protocol/Internet protocol) is the common language of the Internet that allows the disparate network systems to communicate with and understand each other. TCP/IP divides network traffic into individually addressed packets that are routed along different paths. Protocols are the conventions and rules that govern a data communications system. They cover error detection, message length, and transmission speed.

Protocols provide compatibility among different manufacturers’ devices.

The National Science Foundation (NSF) and state governments have subsidized the creation of regional networks. NSFNET’s acceptable use policy initially restricted the Internet to research and educational institutions; commercial use was not allowed. Because of increasing demand, additional backbones were eventually allowed to connect to NSFNET and commercial applications began.

The World Wide Web (WWW or the Web) changed the Internet by introducing a true graphical environment. It has been around since 1989, when it was proposed by Tim Berners-Lee at CERN. The WWW is an Internet service that organizes information using hypermedia. Each document can include embedded references to audio, text, images, full-motion video, or other documents. Comprised of billions of hypermedia documents, the WWW constitutes a large portion of the Internet. Hypermedia is an extension of hypertext. Hypertext allows a user to follow a desired path by clicking on highlighted text, called a “link,” to follow a particular “thread” or topic. Hypermedia documents containing hypertext links allows users to access files, applications, and computers in a nonsequential fashion. It allows for combinations of text, images, sounds, and full-motion video all within the same document. It allows information retrieval with the click of a button. Hypertext is an approach to data management in which data are stored in a network of nodes connected by links. The nodes are designed to be accessed through an interactive browsing system. A hypertext document includes document links and supporting indexes for a particular topic. A hypertext document may include data, audio, and images. This type of document is called hypermedia. In hypertext documents, the physical and logical layouts are usually very different. This is not the case in a paper document. In a paper document, the author of the paper establishes the order and readers follow this pre-established path.

A hypertext system provides users to follow nonsequential paths to access information. This means that information does not have to be accessed sequentially, as in a book. A hypertext system allows the user to make any request that the author or designer of the hypertext provides through links. These link choices are similar to lists of indexes and allow the reader to choose a “custom path.”

Any computer that stores hypermedia documents and makes them available to other computers on the Internet is called a server or a Web server. The computers that request these documents are called clients. A client can be a personal computer at home or a node in a LAN at a university or an organization. The most exciting feature of the Internet and the WWW is that these hypermedia documents can be stored anywhere in the world. A user can easily jump from a site in the United States to a site in Paris, France, all in a few milliseconds.

DOMAIN NAME SYSTEMS

Before a user can begin to navigate the Internet and use it for personal use or e-commerce applications, an understanding of domain name systems (DNS) (also called

domain name servers) is essential. Domain names are unique identifiers of computer or network addresses on the Internet. The following are examples of domain names:

- Netscape.com
- Microsoft.com
- UN.org
- Whitehouse.gov

They come in two forms: English-like names and numeric or IP (Internet protocol) addresses. The Internet Corporation for Assigned Names and Numbers (ICANN) is the nonprofit corporation that assigns and keeps track of these addresses. This was previously performed under U.S. government contract by IANA (Internet Assigned Numbers Authority) and other entities.

IP addresses are less convenient because numbers are more difficult to remember. The English-like names are electronically converted to IP addresses for routing (transferring information from one network to another network). Domain names are used in URLs (uniform resource locator or universal resource locator) to identify a particular Web page. A URL is basically the address of a file or a site on the Internet. For example, in the URL <http://www.csub.edu/~hbidgoli>, the domain name is csub.edu. Every domain name has a suffix that indicates to which top-level domain (TLD) it belongs. In this example the suffix is edu, which stands for educational institutions. Combinations of the letters of the alphabet as well as the numerals 0 through 9 can be used in domain names. The hyphen is the only other character utilized; and spaces are not allowed.

The TLD is the data that comes after “www.” It denotes the type of organization or country the address specifies. TLDs are divided into organizational (generic) and geographic (country code) domains (see Tables 1 through 3).

This system makes it easy to identify the type or location of the organization by looking at the last section of

Table 1: Organizational Domains (Generic Top-Level Domains, gTLD)

.com	Commercial organizations (e.g., Microsoft)
.edu	Education and academic organizations (e.g., California State University)
.int	International organizations (e.g., United Nations)
.mil	U.S. military organizations (e.g., U.S. Army)
.gov	U.S. government organizations (e.g., Internal Revenue Service)
.net	Backbone, regional, and commercial networks (e.g., the National Science Foundation’s Internet Network Information Center)
.org	Other organizations such as research and non-profit organizations (e.g., the Internet Town Hall)

Table 2: Examples of Proposed New Domain Names

.aero	For the aviation industry
.arts	For entities emphasizing cultural and entertainment activities
.biz	For businesses
.coop	For cooperative or cooperative service organizations
.firm	For businesses or firms
.inc	For corporations
.info	For entities providing information services
.law	For those in the legal profession
.museum	For a museum or professionally affiliated personnel
.name	For a noncommercial site associated with a private individual
.pro	For individuals or family names For a site associated with a certified professional or professional organization
.news	For news-related sites
.rec	For entities emphasizing recreation and entertainment activities
.shop	For businesses offering goods and commodities
.store	For electronic storefronts
.web	For entities emphasizing activities related to the WWW
.xxx	For adult content

the domain name. Organization, which is the second field from the right, refers to the name of the organization. A name for a small company is as easy as a large company name. The two leftmost fields of the domain name refer to the computer. This is relevant for large organizations with several levels of subdomains. An example of a relatively complete Internet address is the address of a document in the Web site of the editor-in-chief of the *Handbook*: <http://www.csub.edu/~hbidgoli/books.htm>
A brief explanation from left to right follows:

http—Means of access, hypertext transfer protocol. This is how the majority of Web documents are transferred.

www.csub.edu—This is the address of California State University. It is uniquely defined and differentiated from all other Web sites. WWW is an Internet service that organizes information using hypermedia.

Table 3: Sample Geographic Domains (Country Code Top-Level Domains, ccTLD)

.au	Australia
.br	Brazil
.ca	Canada
.fr	France
.de	Germany
.hk	Hong Kong
.il	Israel
.ir	Iran
.jp	Japan
.kr	Korea (Republic)
.ru	Russia
.es	Spain
.uk	United Kingdom
.us	United States
.va	Vatican City State
.zw	Zimbabwe

~hbidgoli—This is the name of the directory in which the file to be accessed is stored. A server may be divided into a series of directories for better organization.

books.htm—This is the document itself. The htm extension indicates that this is an HTML (hypertext markup language) document. It is the authoring language used to create hypermedia documents on the Web. HTML defines the structure and layout of a Web document by using a variety of tags and attributes. Most hypermedia documents are written in HTML format. Servers that do not support long extensions display “htm,” whereas other servers display “html.”

NAVIGATIONAL TOOLS, SEARCH ENGINES, AND DIRECTORIES

Navigational tools allow the user to surf the Internet and search engines provide access to various resources available on the Internet, such as those that provide library searches for writing a term paper or reservations for an airline ticket. Directories use indexes of information based on key words in the document. As will be discussed elsewhere in this chapter, Yahoo! is a popular directory on the Internet.

The original command language of the Internet was based on computer commands and was difficult to learn for most users. Character-based languages were used for tasks such as downloading files or sending e-mails. These languages are UNIX-based, which meant the user was

required to know the specific syntax of many commands. Everything was communicated in plain text, and graphics, sound, and animation data were not available. The introduction of graphical browsers such as Netscape Navigator changed all of this. Microsoft Internet Explorer and Netscape Navigator are the best-known graphical browsers available for navigating the Internet. Each of these browsers combines powerful graphics, audio, and video capabilities. Each Web server has a “homepage” or a Web site that publishes information about the location. Using character-based browsers such as Lynx, a user will find this information in text form, whereas graphical browsers such as Microsoft Internet Explorer support multimedia information such as images and sound clips.

Navigational Tools

Microsoft Internet Explorer is the most popular graphical browser in the Internet world. With strong marketing support from Microsoft and improvement in its features, Internet Explorer (IE) has gained the lead in the browser market. Netscape Navigator is another graphical browser available for all major operating system platforms. Netscape, similar to IE, provides a true graphical environment that allows the user to surf the Internet using a mouse and the point-and-click technique. Similar to other Windows applications, both IE and Netscape Navigator feature a standard menu bar and toolbar buttons for frequently used commands.

Directories and Search Engines

There are several search engines and directories in use. Yahoo! is the most popular directory and Google, Excite, and Infoseek are three of the most popular search engines. These programs allow a user to scan the Internet and find information through the use of key words or phrases. A search could be for research for a term paper, finding an exotic antique for a personal collection, or anything in between. The following paragraphs briefly describe Yahoo!, Google, and Excite.

Jerry Yang and Dave Filo founded Yahoo! in April 1994. Yahoo! is one of the best-known directories on the Internet. A directory is a search service that classifies Web sites into a hierarchical, subject-based structure. For example, Yahoo! includes categories such as art, business, and entertainment. These categories are organized by topic. The user can go to a category and then navigate for specific information. Yahoo! also includes an internal search engine that can expedite the search process. Yahoo! soon expanded to offer other services and became a portal on the Internet. A portal or gateway for the WWW is an application that serves as an information search organizer. Portals provide a single-point integration and navigation through the system. Portals create an information community that can be customized for an individual or a corporation. Portals serve as the major starting sites for many individuals who are connecting to the Internet. Some of the services offered by Yahoo! include Yahoo! Travel, Yahoo! Classifieds, Yahoo! Pager, and Yahoo! Autos.

Excite, Inc. was founded in June 1994. Its basic mission is to provide a gateway to the Internet and to organize, aggregate, and deliver information to meet users' needs. The Excite Network, including the Excite and WebCrawler brands, contain a suite of specialized information services that combine proprietary search technology, editorial Web reviews, aggregated content from third parties, and bulletin boards. The Excite Network serves as a central place for consumers to gather and interact during each Web experience. Excite PAL is an instant paging service. By entering the names and e-mail addresses of friends, family, and colleagues into Excite PAL, a user can find them online.

Larry Page and Sergey Brin, two Stanford Ph.D. candidates, founded Google in 1998. Google helps its users find the information they are looking for with high levels of ease, accuracy, and relevancy. The company delivers its services to individuals and corporations through its own public site, <http://www.google.com>, and through co-branding its Web search services. To reach the Google Web site, the user simply types www.google.com (its URL) into the location box of the Web browser and presses the Enter key. At the initial Google screen, the user enters the desired search item(s), for example “computer viruses,” and then again presses the Enter key or clicks on the “Google Search” button. In a few seconds, the items that closely match the search items will be displayed. Although the Web site's default language is English, the user can choose a different language if desired.

INTERNET SERVICES THAT SUPPORT ELECTRONIC COMMERCE

Electronic mail (e-mail), news and discussion groups, Internet relay chat (IRC), instant messaging, and the Internet phone are among the services offered by the Internet that could enhance a successful e-commerce program. Other chapters in the *Handbook* will provide a more in-depth discussion of these services. In this chapter a brief overview of these services is presented (Bidgoli 2002).

E-mail is one of the most popular services available on the Internet. Using e-mail, a user can create a message electronically and send it via the communications media. New products and services can be announced to customers using e-mail. Confirmations can be sent using e-mail and also many business communications can be effectively performed using e-mail. When a user sends an e-mail, the message usually stays in the recipient's e-mail server until the recipient reads it. In most e-mail systems, the receiver is able to store the e-mail message in an electronic folder for future reference. E-mail is fast and will get to the recipient's computer in a matter of seconds or minutes. All that is needed to send an e-mail message is the e-mail address of a recipient. A user can also send a single e-mail message to a group of people at the same time. A user can apply all the word processing tasks such as spell-checking and grammar correction before sending the e-mail message. Document files and/or multimedia files can be attached to an e-mail message and a user could ask for delivery notification. With e-mail, a

user can usually establish various folders with different contents and send a particular e-mail to a specific group. Using e-mail enables a user to establish an effective message-distribution system for advertising products and services. (For detailed information on this topic, consult “E-mail and Instant Messaging”.)

The Internet brings together people with diverse backgrounds and interests. Discussion groups exist to enable groups of people with common interests to share opinions and ideas. Each person in a discussion group can post messages or articles that can be accessed and read by others in the group. Newsgroups can be established for any topic or hobby and allow people to get together for fun and entertainment or for business purposes. For example, a user may join a newsgroup where the users are interested in ancient civilization, or a user may join a newsgroup that can help in writing and debugging a computer program in a specific programming language. Newsgroups can serve as an effective advertising medium in an e-commerce environment. For detailed information on this topic, consult “Online Communities”.

Internet relay chat (IRC) enables a user to interactively communicate in written form with other users from all around the world. It is similar to a coffee shop where people sit around a table and start chatting. The three major differences between this electronic coffee shop and a real coffee shop are that there is no coffee, the user does not see the people that he/she is chatting with, and IRC leaves a “chat trail,” which can be used later. However, a user is able to participate in many different discussions with people anywhere in the world who have the same interest. (For detailed information on this topic, consult “Internet Relay Chat (IRC)”.)

Instant messaging (IM) is a communication service that enables a user to create a private chat room with another user. Different instant messenger applications offer different capabilities. They typically alert a user whenever someone on the user’s private list comes online so that a user may initiate a chat session with that particular individual. (For detailed information on this topic consult “E-mail and Instant Messaging”.)

Internet telephony is the use of the Internet rather than the traditional telephone-company infrastructure to exchange spoken or other audible information. Because access to the Internet is available at local phone connection rates, an international or other long-distance call will be much less expensive than through the traditional calling arrangement. This could be a major cost savings for an e-commerce site that offers hotline, help desk, and other services. (For detailed information on this topic, consult “Voice over IP (VoIP)”.)

Three new services are now or will soon be available on the Internet:

1. The ability to make a normal voice phone call (despite whether the person called is immediately available; that is, the phone will ring at the location of the person called). In most of the technologies currently available, a “phone meeting” must be arranged in advance, and then both parties log onto the Internet at the same time to conduct the conversation.

2. The ability to send fax transmissions at very low cost (at local call prices) through a gateway point on the Internet in major cities.
3. The ability to leave voice mail at a called number.

Another recent application of the Internet for both personal as well as business use is called **blog** and **blogging**. Blog, short for Weblog, is a journal or newsletter that is frequently updated and intended for general public use. Blogs generally represent the personality and the interest of the author (creator) on the Web site itself. They usually include philosophical reflections, opinions on the Internet, and social or political issues. A blog also applies to Web sites dedicated to a particular topic and being updated with the latest news, views, and trends. They are becoming a popular source of online publication, especially regarding political information, opinions, and alternative news coverage. Automated tools have made the creation and maintenance of blogs an affordable and relatively easy task, making them available to individuals with minimum technical backgrounds. Blogs are now popular for business as well as personal uses. Blogs are sometimes used as a communications tool for small groups of people to keep in touch with each other. The activity of updating a blog is called “blogging” and the individual who keeps a blog is called a “blogger.”

WHAT IS AN INTRANET?

The excitement created by the Internet has been transferred to another growing application called intranets. In simple terms, whatever a user can do with the Internet, a user should also be able to do with an organization’s private network, or intranet.

An intranet provides users with easy-to-use access that can operate on any computer regardless of the operating system in use. Intranet technology helps companies disseminate information faster and more easily to both vendors and customers and can be of benefit to the internal operations of the organization. Although intranets are relatively new, they have attracted a lot of attention in a very short time (Bidgoli, 1999, 2002).

An intranet uses Internet and Web technologies to solve organizational problems traditionally solved by proprietary databases, groupware, scheduling, and workflow applications. An intranet is different from a LAN, MAN, (metropolitan area networks) or WAN (wide area network), although it uses the same physical connections. An intranet is an application or service (or set of applications or services) that uses the computer networks (the LANs, MANs, and WANs) of an organization, and that is how it is different from LANs, MANs, and WANs. The intranet is only logically internal to the organization. Intranets can physically span the globe, as long as access is specifically defined and limited to the specific organization’s community of users behind a firewall or a series of firewalls.

In a typical intranet configuration, all users in the organization can access all the Web servers. The system administrator must define the degree of access for each user. They can constantly communicate with one another and post information on their departmental Web servers.

However, usually a firewall (or several firewalls) separates these internal networks from the Internet (the worldwide network).

Within these departmental Web servers, individual employees can have their own Web pages, divided by department. For example, the following departments each may include several Web pages as parts of the organization's intranet program:

finance
human resources
information services
manufacturing
marketing
sales

So what is an intranet? In simple terms, an intranet is a network within the organization that uses Internet technologies (TCP/IP, HTTP, FTP [file transfer protocol], SMTP [simple mail transfer protocol], HTML, and XML [extensible markup language]) for collecting, storing, and disseminating useful information throughout the organization. This information supports e-commerce activities such as sales, customer service, and marketing.

Employees can find internal information and they can bookmark important sites within the intranet. Furthermore, individual departments can create their own Web sites to educate or inform other employees about their departments by implementing intranet technology. For example, staff members in the marketing department can present the latest product information, and manufacturing staff members can post shipping schedules and new product designs. The human resources department can post new jobs, benefit information, new promotions, and information on the 401K plan. The finance and accounting departments can post cost information and other financial reports on their sites. The president's office might post information about the next company-wide gathering on its site. This information collectively supports a successful e-commerce program.

INTERNET VERSUS INTRANETS

The Internet is a public network. Any user can access the Internet, assuming the user has an active account with an ISP. The Internet is a worldwide network, whereas intranets are private and are not necessarily connected to the Web. Intranets are connected to a specific company's network, and usually the users are the company's employees. An intranet is separated from the Internet through the installation and use of a firewall (or several firewalls). Intranets usually have higher throughput and performance than the Internet and are usually more secure than the Internet.

Apart from these differences, the two have a lot in common. They both use the same network technology, TCP/IP, and they both use browsers for accessing information. They both use documents in HTML and XML formats, and both are capable of carrying documents with multimedia formats. Also, they both may use the Java

Table 4: Internet versus Intranet

Key Feature	Internet	Intranet
User	Anybody	Employees only
Geographical scope	Unlimited	Limited to unlimited
Speed	Lower than that of an intranet	Usually higher than that of the Internet
Security	Lower than that of an intranet	Usually higher than that of the Internet
Technology used	TCP/IP	TCP/IP
Document format	HTML	HTML
Multimedia capability	Could be lower than that of an intranet	Could be higher than that of the Internet

programming (or its derivatives) language for developing applications.

Intranets may or may not use any of the technologies beyond HTML, that is, Java programming, JavaScript or VBScript, Active X, Dynamic HTML, or XML. One of the advantages of an intranet is that because the organization can control the browser used, it can specify a browser that will support the technologies in use. Beyond Web documents, the organization can also specify the use of the Internet phone, e-mail, video conferencing, and other Web technologies supported by the chosen browser. Table 4 summarizes the similarities and differences of these two technologies.

SELECTED APPLICATIONS OF AN INTRANET

A properly designed intranet can make the type of information listed in Table 5 available to the entire organization in a timely manner. This information directly or indirectly can improve the efficiency and effectiveness of an organization (Bidgoli, 1999, 2002).

Many internal applications in use today can be easily converted to an intranet or can be supported using an intranet. Human resources applications, such as job information, name and phone number lists, and medical benefits, can be securely displayed on a human resources intranet site. The finance site might present information on time cards, expense reports, or credit authorization. Employees can easily access the latest information on a server. With e-mail, e-mail distribution lists, and chat lines, employees can retrieve meeting minutes and much more.

Intranets also allow organizations to evolve from a "calendar" or "schedule"-based publishing strategy to an "event-driven" or "needs-based" publishing strategy. In the

past, companies published an employee handbook once a year. Traditionally, the handbooks would not be updated until the following year even though they may have been outdated as soon as they arrived on the users' desks. Some of these organizations sent a few loose pages as an update every so often. The employee is expected to add these pages to the binder. After a while, these materials become difficult to go through to retrieve specific information.

With an intranet publishing strategy, information can be updated instantly. If the organization adds a new mutual fund to the 401K programs, content on the benefits page can be updated immediately to reflect that change, and the company internal homepage can include a brief announcement about the change. Then, the employees have the new information at their desktops as soon as they look up the 401K programs.

Intranets dramatically reduce the costs and time of content development, duplication, distribution, and utilization. The traditional publication model includes a multistep process including

creation of content
production of the draft
revision of the draft
final draft preparation
migration of the content to the desktop publishing environment
duplication
distribution

However, intranet technology reduces the number of steps to only two (it eliminates the duplication and distribution steps):

creation of content
migration of content to the intranet environment

However, content still needs review and approval regardless of the medium used for delivery.

WHAT IS AN EXTRANET?

Interorganizational systems (IOSs) facilitate information exchange among business partners. Some of these systems, such as electronic funds transfer (EFT) and e-mail, have been used in traditional businesses as well as in the e-commerce environment. Among the most popular IOSs are electronic data interchange (EDI) and extranets. Both EDI and extranets provide a secure connection among business partners. Their roles in business-to-business e-commerce are on the rise. These systems create a seamless environment that expedites the transfer of information in a timely matter.

Some organizations allow customers and business partners to access their intranets for specific business purposes. For example, a supplier may want to check the inventory status or a customer may want to check account balances. These networks are referred to as extranets. It should be noted that an organization usually makes only a portion of its intranet accessible to these external parties. Also, comprehensive security measures must ensure that access is given only to authorized users and trusted business partners.

An extranet is defined as a secure network that uses Internet and Web technology to connect two or more intranets of business partners, enabling business-to-business, business-to-consumer, consumer-to-consumer, and consumer-to-business communications. Extranets are a network service that allows trusted business partners to secure access to useful information on another organization's intranet. Table 6 provides a comparison of the Internet, intranets, and extranets (Bidgoli, 2002; Fletcher, 1997).

There are numerous applications of extranets in the e-commerce world. Toshiba America Inc. is an example of a company that uses an extranet. Toshiba has designed an extranet for timely order-entry processing. Using this extranet, more than 300 dealers can place orders for parts until 5 p.m. for next-day delivery. Dealers can also check accounts receivable balances and pricing arrangements, read press releases, and much more. This secure system

has resulted in significant cost savings and has improved customer service (Jones, 1998).

Another example of an extranet is the Federal Express Tracking System (<http://www.fedex.com>). Federal Express uses its extranet to collect information and make it available to its customers over the Internet. The FedEx Web site is one of the earliest and best-known examples of an extranet—an intranet that is opened to external users. The customer can access FedEx's public site, enter a package's tracking number, and locate any package still in the system. Using this system, a customer can enter all the information needed to prepare a shipping form, obtain a tracking number, print the form, and schedule a pickup.

Extranets provide very secure, temporary connections over public and private networks between an organization and a diverse group of business partners outside of the organization. These groups may include

customers
vendors
suppliers
consultants
distributors
resellers
outsourcers, such as claim processors, or those with whom the company is doing research and development (R&D) or other collaborative work, such as product design.

Extranets not only allow companies to reduce internet-working costs, they also provide companies with a competitive advantage, which may lead to increased profit. A successful extranet program requires a comprehensive security system and management control. The security system should provide comprehensive access control, user-based authentication, encryption capability, and comprehensive auditing and reporting capabilities.

An extranet offers an organization the same benefits that an intranet offers while also delivering the benefits that derive from being linked to the outside world. Some of the specific advantages of an extranet include (Bidgoli, 2002):

Coordination—An extranet allows for improved coordination among participating partners. This usually includes suppliers, distributors, and customers. Critical information from one partner can be made available so that another partner can make a decision without delay. For example, it is possible for a manufacturer to coordinate its production by checking the inventory status of a customer.

Feedback—An extranet enables an organization to receive instant feedback from its customers and other business partners. It gives consumers an opportunity to express their views about products or services before those products or services are even introduced to the market.

Customer satisfaction—An extranet links the customer to an organization. This provides the customer with more information about products, services, and the organization in general. This also makes ordering products or services as easy as a click of the mouse. Expediting

Table 6: Comparison of the Internet, Intranets, and Extranets

	Internet	Intranet	Extranet
Access	Public	Private	Private
Information	Fragmented	Proprietary	Proprietary
Users	Everybody	Members of an organization	Groups of closely related companies, users, or organizations

business-to-business e-commerce is definitely one of the greatest benefits of an extranet.

Cost reduction—An extranet can reduce the inventory costs by providing timely information to the participants of a supply network program. Mobil Corporation, based in Fairfax, Virginia, designed an extranet application that allows distributors throughout the world to submit purchase orders. By doing this, the company significantly increases the efficiency of the operation. It also expedites the delivery of goods and services (Maloff, 1997).

Expedite communication—Extranets increase the efficiency and effectiveness of communication among business partners by linking intranets for immediate access to critical information. A traveling salesperson can receive the latest product information remotely before going to a sales meeting. A car dealer can provide the latest information to a customer on a new model without making several phone calls and going through different brochures and sales manuals.

SELECTED INTERNET APPLICATIONS

Several segments of service industries have significantly benefited from the Internet and its supporting technologies. The Internet has enabled these businesses to offer their services and products to a broad range of customers with more competitive prices and convenience. The Internet offers numerous tools and advantages to these businesses to sell their products and services all over the world. Table 7 lists popular Internet applications.

In the following pages, some of the major beneficiaries of the Internet and e-commerce will be reviewed.

Tourism and Travel

Tourism and travel industries have significantly benefited from various Internet and e-commerce applications. As an example, the Tropical Island Vacation (<http://www.tropicalislandvacation.com>) homepage directs prospective vacationers to an appropriate online brochure after vacationers respond to a few brief questions about the type of vacation they would like to take. Customers simply point and click on appealing photographs or phrases to explore further. Another example is Zeus Tours (<http://zeustours.com>), which has been very effective at offering unique and exciting tours, cruises, and other travel packages online. Many Web sites allow customers to reserve tickets for planes, trains, buses, cruises, hotels, and resorts. Sites such as biztravel.com (<http://biztravel.com>) allow its business customers to plan a trip, book a vacation, gather information on many cities, gather weather information, and much more. Expedia.com, Travel.com, Travelocity.com, Priceline.com, hotels.com, and Yahoo! Travel are other examples of sites that offer all types of travel and tourism services.

Publishing

Many major textbook publishers in the United States and Europe have homepages. An interested individual can read the major features of forthcoming books or books in print before ordering them. The Web sites of some

Table 7: Popular Internet Applications

Marketing and advertising
Distance learning (e-learning, virtual learning)
Electronic conferencing
Electronic mail (e-mail)
Electronic posting
Healthcare management
Home shopping
Interactive games
Inventory management
News groups and discussions
News on demand
Online banking
Online employment
Online software distribution
Online training
Online politics (voting, participating in political forums, chat groups, and using the Internet for political fund raising)
Remote login
Sale of products and services
Telecommuting
Transferring files with FTP
Video on demand
Videophones
Online demonstrations of products and services throughout the world
Virtual reality games
Online request for proposal (RFP), request for quotes (RFQ), and request for information (RFI)

publishers include a sample chapter from specific books, or entire books that can be read online for free for 90 days, whereas others allow online customers to purchase portions of a book rather than the entire book. The Web site of John Wiley & Sons (<http://wiley.com>), publisher of *The Handbook of Computer Networks*, allows a prospective buyer to search the online catalog based on the author's name, the title of the book, and so forth. When the desired book is found, it can be ordered online.

Higher Education

Major universities also have homepages. An interested individual can go on a tour of a university and read about different departments, programs, faculty, and academic

resources. Many universities throughout the world are creating virtual divisions that offer entire degree programs on the Internet. Many professional certificate programs are also offered through the Internet. These programs and courses provide a real opportunity and convenience for individuals in remote areas and individuals who cannot attend regular classes to enroll in these courses. They also provide a source of revenue for many colleges and universities that are facing enrollment decline in their service areas. They also allow renowned experts to teach courses to broad geographic audiences.

Real Estate

Numerous real estate Web sites provide millions of up-to-date listings of existing and new homes for sale throughout the world. These sites are devoted entirely to buying and selling real estate. The buyer or seller can review neighborhoods, schools, and local real estate prices. These sites allow the customer to find a realtor, find brokerage firms, and learn many home-buying tips. Some of these sites offer or will soon offer "virtual tours." These virtual tours enable a buyer to view a prospective property from distance. This is achieved by using virtual reality technologies. Some of the services offered by a typical real estate site are listed below:

- appraisal services
- buying
- checking neighborhood profiles
- checking schools profiles
- financing
- home improvement advice
- obtaining credit reports
- posting a free listing
- renting services
- selling advice, and much more

Table 8 lists examples of major real estate sites.

Employment

Employment service providers have established Web presences. Table 9 provides a listing of some of the popular sites to use for finding or recruiting for a job, especially if it involves information technology.

Banking and Brokerage Firms

Online banking is here. Many U.S. and Canadian banks and credit unions offer online banking services. Although online banking has not been fully accepted by customers, many banking-related resources are being utilized. For example, many banks use e-mail to communicate with their corporate customers. E-mail is a less expensive and more convenient alternative to a telephone call, especially for long distance communications. Financial reports for banks can be easily distributed via e-mail to mutual fund investors or customers.

The banking industry's ultimate goal is to carry out many of their transactions through the Internet.

Table 8: Examples of Online Real Estate Sites

Prudential California (http://www.prudential.com) provides wireless listing services and property data for agents.
ERA (http://www.era.com) is an Internet-based application with listing information for agents.
Century 21 (http://www.century21.com) is an electronic system for tracking agent referrals worldwide and also offers home buying, home selling, financing, and property listings.
Re/Max (http://www.remax.com) is a contact management tool for agents that interfaces with personal digital assistant (PDA) devices.
Homestore.com (http://www.homestore.com) provides a listing of properties throughout the United States.
Mortgage Expo.com (http://www.mortgageexpo.com) provides a listing of home lenders throughout the United States.

Table 9: Some of the Popular Sites to Use for Finding or Recruiting for a Job

http://www.careermosaic.com
http://www.hotjobs.com
http://www.monster.com
http://www.webhire.com
http://www.dice.com
http://www.guru.com

Consumer acceptance is the major factor that has kept this business from exploding. It is generally believed that a secure nationwide electronic banking system is almost in place. Soon people will be able to use their personal computers (PCs) and the Internet to do all types of banking activities.

Digital signatures are a key technology for the banking and brokerage industry because they provide an electronic means of guaranteeing the authenticity of the sending party and assurance that encrypted documents have not been changed during transmission. The current mergers and acquisitions taking place and the frequent downsizing within the financial industry are two reasons to support Internet banking. Table 10 lists some of the services available via the Internet for banking activities.

Many brokerage firms offer stock and other security transactions online. They provide quotations for stocks, bonds, and other securities. To encourage more customers to use these services, they may offer discounts.

Software Distribution

Several major software vendors offer software on the Internet. Customers can view listings of available software, order, and designate an installation time. Nearly all

Table 10: Some of the Services Available via the Internet for Banking Activities

24/7 customer service by e-mail
Accessing current and old transactions
Categorizing transactions and producing reports
Exporting banking data to popular money management software
Obtaining online funding for checking accounts
Obtaining online mortgage and certificate of deposit applications
Obtaining written guarantee against frauds and late payments
Obtaining instant approval for personal loans
Obtaining interactive guides to aid selection of a proper banking product or service
Obtaining interactive tools for designing a savings plan, choosing a mortgage, and/or obtaining online insurance quotes all tied to applications
Obtaining online application for both checking and savings accounts
Obtaining online forms for ordering checks and issuing a stop payment
Obtaining free checks and free foreign ATM use
Obtaining IRA and brokerage account information
Obtaining loan status and credit card account information online
Paying bills
Paying credit card accounts
Transferring funds
Viewing digital copies of checks

hardware manufactures offer drivers and patches as updates on the Web. Microsoft and several other software companies already offer free software via the Internet. Routine downloading of the Netscape Navigator and Microsoft Internet Explorer browser applications are two good examples. Both are relatively small programs. In contrast is the Microsoft Office Suite, which would take significantly longer to download through an online application service provider. Given today's communications throughput and bandwidth limitations, program size definitely poses a challenge to online software distribution.

A successful application in this area is the distribution of antivirus programs over the Internet. Several of the vendors of this software application are already using the Internet to sell their software to prospective buyers. A major advantage of this method is the frequency of automatic updates that vendors provide for their customers. The Internet makes this process a cost-effective venture for both the vendors and the customers.

The development of online copyright-protection schemes continues to be a challenging problem. If users need an encryption code to "unlock" software, backups may not be possible. However, the odds are in favor of online software distribution because it provides an inexpensive, convenient, and speedy method of purchase and implementation (Cross, 1994; Hayes, 1995).

Healthcare

Electronic patient records on the Internet could provide complete medical information and allow physicians to order laboratory tests, admit patients to hospitals, refer patients to other physicians or specialists, and order prescriptions. Test and consultation results would be directed automatically to electronic patient records. The advantages of this approach include the fact that all patient information would be accessible from one central location. Another positive side of this application is that it would allow easy access to critical health information. Imagine a person who is far away from home and has a serious health problem because of injury or other causes. Any physician in any location will be able to download the complete medical history of this patient and prescribe a suitable treatment in a short period. However, these systems may offer disadvantages, such as potential problems with information privacy, accuracy, and currency.

Telemedicine (<http://telemedtoday.com>) may provide the medical profession with the ability to conduct remote consultation, diagnosis, and conferencing. This could result in major annual savings in travel costs and overhead for medical care professionals. As part of the information superhighway, a personal health information system (PHIS) could conceivably provide interactive medical tools to the public. Public kiosks located in shopping malls would be equipped with user-friendly computer equipment for Internet access. Patients would be prompted through the diagnosis procedure by a series of interview-like questions. Premature onset of disease could be minimized with this pre-emptive and proactive approach (Anonymous, 1994).

Virtual medicine on the Internet may allow specialists at major hospitals to operate on patients remotely. Telepresence surgery, as this is called, would allow surgeons to operate all over the world without physically traveling anywhere. A robot would perform the surgery based on the digitized information sent by the surgical specialist via the Internet. Robots would have stereoscopic cameras to create three-dimensional images for the surgeon's virtual reality goggles. Physicians would operate in a virtual operating room. Tactile sensors on the robot would provide position information to the surgeon so that he/she can feel what the robot feels. Already, prescription drugs are sold online and there are several Web sites that offer medical services (Bazzolo, 2000).

Politics

In the United States in recent years, the Internet has become a major promotional tool for all major political contenders in races for the White House, the House of Representatives and Senate, and other races. Political

candidates use the Internet to announce the platforms that they are running on, their major differences with their opponents, their leadership styles, forthcoming debates, political events, and so forth. They even use the Internet for fund-raising.

The Internet may facilitate empowering voters and revitalizing democracy. Twenty-first century citizens may vote using a computer connected to the Internet, resulting in increased voter participation. Part-time legislators may have remote access to Washington and yet remain geographically close to the constituents they represent. Of course, an identification system would have to be in place, which could very likely use voice identification, face scan, finger image, hand geometry, or some other form of biometric verification technology. If such a system becomes available, then the security of the voting application, security of voting results, and counting accuracy must be carefully analyzed. Currently, the U.S. House of Representatives is attempting to put all pending legislation online. Presidential documents can be found on the Internet. Full-text versions of speeches, proclamations, executive orders, press briefings, daily schedules, the proposed federal budget, healthcare reform documents, and the Economic Report of the President are available. There are a number of repositories of this information that can be found using search engines.

CONCLUSION

This chapter reviewed the basics of the Internet and information superhighway. Navigational tools, search engines and directories were discussed and then the chapter explored intranets and extranets as two popular applications of the Internet that are being used in the e-commerce environment. The chapter concluded with a review of several popular applications of the Internet in selected fields of the service industry including tourism and travel, publishing, higher education, real estate, employment, banking and brokerage firms, software distribution, healthcare and politics.

GLOSSARY

ARPANET (Advanced Research Projects Agency Network): Started in 1969 and continued through 1990 as the basis for early networking research and as a central backbone network during development of the Internet.

Blog, short for weblog: A journal or newsletter that is frequently updated and intended for general public use.

Directories: An index of information based on key words in a document. Yahoo! is a popular directory on the Internet.

Domain name systems (or domain name servers, DNS): Unique identifiers of computer or network addresses on the Internet. Whitehouse.gov and csu.edu are two examples. The first one uniquely identifies the White House and the second identifies California State University in Bakersfield.

Extranet: A secure network that uses the Internet and Web technology to connect two or more intranets of

trusted business partners, enabling business-to-business, business-to-consumer, consumer-to-consumer, and consumer-to-business communications.

Hypermedia: This allows links for combinations of text, images, sounds, and full-motion video in the same document. It allows information retrieval with a click of a button.

Hypertext: This provides users with nonsequential paths to access information whereby information does not have to be accessed sequentially, as in a book.

Internet: A collection of millions of computers and networks of all sizes. Simply put, the Internet is the "network of networks."

Intranet: A network within the organization that uses Web technologies (TCP/IP, HTTP, FTP, SMTP, HTML, XML, and its variations) for collecting, storing, and disseminating useful information throughout the organization.

Navigational tools: These allow the user to surf the Internet; Microsoft Internet Explorer and Netscape Navigator are two popular examples.

Search engines: These provide access to various resources available on the Internet, such as library searches for writing a term paper or resources for making a reservation for an airline ticket. Google.com is an example.

URL (uniform/universal resource locator): The address of a file or a site on the Internet used to identify a particular Web page.

INTRODUCTION

In his prophetic and now famous 1945 *Atlantic Monthly* article, Vannevar Bush noted that inefficiencies in the exchange of new theory and discovery slowed scientific progress. He envisioned a system for rapid dissemination and organization of scientific information, instantly available to all who seek it, which he named the “memex.” The memex was to be a “transparent platen” on which books, pictures, periodicals, newspapers, longhand notes, photographs, and other information would be provided to anyone who had access to the machine and knowledge of its indexing system. He foresaw scientists accessing information from around the world at unprecedented rates based on the same associational principles by which the human mind operates. Further, he saw scientists and professional data miners recording their journey through the data such that anyone who was interested could follow. A half century after the article appeared, his vision was realized in the form of the World Wide Web and related Internet technologies. This is the story of the inventors, ideas, and innovations that made Bush’s vision a reality.

The Internet was created by a collection of visionaries and executed by hundreds of individuals whose contributions helped develop the technology (for a timeline, see Figure 1). The result is the technological and intellectual infrastructure of the Information Age, supporting the majority of the emerging economy for the 21st century. How did this marvel come to be? This chapter tells the story of the creation of the Internet and the World Wide Web. Guided by a unique vision of computer communication in a world of calculating machines and driven by the desire to solve a series of complex engineering problems, the Internet emerged as an open-architecture marvel of scientific and engineering cooperation. The principles that guided the creation of the Internet typify the finest

realization of American cooperative scientific ideals. The Internet as we know it is the result of dedication to a set of core principles: that this communication system be the result of cooperation among interested parties, be open to new ideas, and be scalable. The vision was realized in a series of fits and starts, problems and solutions, ideas and the implementation of those ideas by engineers pushing the boundaries of current technology. It is the result of intellectual and political argumentation and compromise, funded by the military-industrial complex, but realized in the world of the academic. This chapter can hardly be called a history, though, because the open architecture of the Internet encourages further experimentation. Instead, this chapter can best be called a beginning.

A UNIQUE VISION

The Industrial Revolution of the nineteenth century brought about the development of technologies that allowed people, ideas, and products to travel across long distances in a short amount of time, facilitating exploration of scientific and technological frontiers (Moschovitis, Poole, Schuyler, and Senft 1999). Nineteenth-century scientific exploration laid the groundwork for the technological antecedents of modern computing and networking that came into popular use in the first half of the twentieth century, from the telephone to such early colossal computers as ENIAC. These early twentieth-century technologies were similarly dedicated to two goals: the desire to increase the ease of communication across distance and the desire to provide resources that assist humans in the efficient processing of information. However, it was the charged atmosphere surrounding the Cold War that provided the initial momentum to bring these two goals together as matters of national defense and pride.

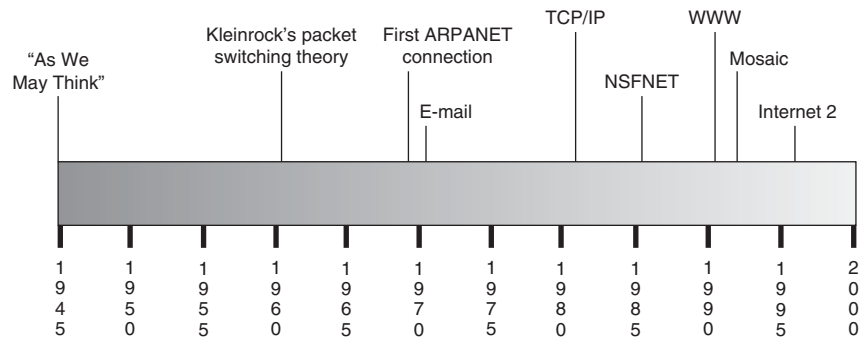

Figure 1: Timeline of major Internet events

The Marriage of Science and National Defense

By the late 1940s, the Soviet Union had long-range bombers and atomic capabilities. The Department of Defense, under President Harry Truman, enlisted the help of researchers at RAND and the Massachusetts Institute of Technology (MIT) Lincoln Laboratory to develop the Semi-Automated Ground Environment (SAGE) to detect and counteract Soviet airborne attacks (Segaller 1998). SAGE consisted of 23 direction centers linked back to a central computer; the first fully deployed data communication system between computers. It was at this time, the 1940s and early 1950s, that many of the graduate students and scientists at MIT and Lincoln gained the preliminary experience necessary to create networked computers, including connecting computers to phone lines, using computers to handle real-time data coming from antennas and submarines, digitizing communications, and developing and refining faster, more reliable computers (Segaller 1998).

On October 4, 1957, the Soviets launched Sputnik, the first human-made Earth satellite. The Eisenhower administration's fears of technological weakness came to the surface; the Soviet Union was leading the United States in space technology. Science and technology were instantly wed to national defense and the relationship was thrust into the social and political limelight as President Eisenhower, a supporter of science prior to Sputnik, ensured the public that he was committed to providing massive support for defense research. Eisenhower immediately convened a meeting of his Presidential Science Advisory Committee, and in November 1957, he appointed MIT president James Killian as the official presidential scientific advisor (Hafner & Lyon 1996).

ARPA Is Created

Working closely with President Eisenhower and the Secretary of Defense, Neil McElroy, Killian recommended that Congress create the Advanced Research Projects Agency (ARPA) within the Department of Defense (Zakon 2002). Congress quickly approved start-up funds of \$520 million and an annual budget of \$2 billion. In early 1958, ARPA was officially established as the U.S. government's sole research agency dedicated to the development of space-related military technology. The vigorous national commitment to beating the Soviets in defense and space technology had officially begun for the government and

the American public. Although much of the computer-related funding by the mid-1960s came from the Department of Defense, many of the scientists involved with ARPA used the surge in governmental support as an opportunity to realize their academic pursuits (Abbate 1999). The intersection of military, governmental, academic, and public goals remains an integral part of the creation and maintenance of the modern Internet.

In 1958, the National Aeronautics and Space Administration (NASA) was split from the computer research section at ARPA in order to oversee all space exploration and missile research and to assure that this technology was developed in the civilian sector. ARPA was left with the relatively meager budget of about \$150 million. However, the removal of space and missile research from ARPA's agenda allowed researchers to focus greater effort on the emerging fields of computer science and information processing. At this point, ARPA directly funded most of the top computer science researchers in the United States and at least partially funded projects at most of the research centers and universities engaged in high-tech endeavors (Hafner & Lyon 1996).

Networking Visions Emerge

In 1962, the first director of ARPA, Jack Ruina, hired mathematician, behavioral psychologist, and computer science connoisseur Joseph C. R. "Lick" Licklider to head ARPA's command and control division. In his groundbreaking essay "Man-Computer Symbiosis," Licklider (1960) had proposed the idea of interactive computing, an idea taken for granted by every personal computer user today. Inspired by the visionary works by Bush (1945) and Alan Turing (1950) on the use of computers to augment human intelligence, Licklider also prophesized that computers would become more than mere calculating tools. He envisioned that the relationship between humans and computers would evolve and result in cooperative decision making and problem solving in real time, that is, without the long delays that characterized computing in the 1950s (Licklider 1960).

In addition to envisioning the eventual state of interaction between human and computer, Licklider was the first to envision the linking of many computers at locations distant from each other. Nine years before it became a reality, he wrote: "It seems reasonable to envision . . . a 'thinking center' that will incorporate the functions of present-day libraries together with anticipated advances

in information storage and retrieval. . . . The picture readily enlarges itself into a network of such centers, connected to one another by wide-band communication lines and to individual users by leased-wire services. In such a system, the speed of the computers would be balanced, and the cost of the gigantic memories and the sophisticated programs would be divided by the number of users" (Licklider 1960, 15).

Licklider expanded on the idea of a system of linked computers in a series of historically important memorandums written with Wesley Clark, entitled "On-Line Man Computer Communications" (Licklider and Clark 1962). They wrote of a "galactic network" where computers and information would be linked and accessible to everyone. MIT's Larry Roberts, a successor of Licklider's, commented that, "[t]he vision [of linking many computers together] was really Lick's originally. Lick saw this vision in the early sixties. He didn't have a clue how to build it. But he knew it was important" (Segaller 1998, 40).

Licklider's outline of an interactive network linking people and resources together was also seen as a possible solution to a practical problem surrounding computing in the early 1960s: stretched resources. In the 1950s and 1960s, ARPA had commissioned laboratories around the country to carry out a variety of projects in science and technology, providing each with large, expensive mainframe computers manufactured by different companies. Individual laboratories altered their computers, adding different applications, packages, and hardware, and each subsequent laboratory wanted the latest computing capabilities available. The enormous costs of building separate units for each project began to snowball.

In early 1966, Robert Taylor, director of the Information Processing Techniques Office (IPTO, the computing division of ARPA), proposed a remedy to the scarce resource problem that incorporated the latest research and developments: Build a system of electronic connections between research computers at different geographical locations across the country to allow convenient, quick, and inexpensive sharing of resources between many scientists (Hafner and Lyon 1996). The idea of networking was already being implemented on a smaller scale, for example linking two computers together (Marill and Roberts 1966), but nothing that approached the scale or complexity of Taylor's proposition had been attempted so far. The technology of the time did support such a notion. In 1958, communications engineers at Bell Laboratories had built the modulator-demodulator, or simply "modem" (Anderberg 2002). The modem made it possible to convert data from the digital computer format into the analog telephone line format, send it over existing phone lines, and translate it back to digital computer format. By using the long-distance infrastructure already in place, the task of linking many computers for the purpose of sharing resources was indeed an attractive and financially sound proposal. In 1966, Taylor pitched the idea to his boss, ARPA Director Charlie Hertzfeld, and received approval and financial support to build the experimental network. In 1967, Taylor enticed Larry Roberts to leave Lincoln Lab and join him at ARPA to begin planning the proposed computer network, which would soon become known as the ARPANET (Segaller 1998).

Networking: From Theory to Practice

Although Licklider imagined what a distributed, interactive computer network could accomplish and Taylor imagined what problems it could solve, Leonard Kleinrock had theorized in 1961 the new communication technology that could make such a network possible (Hafner and Lyon 1996). Two major obstacles to creating a long-distance computer network were (a) being able to receive and process data over existing phone lines fast enough to allow efficient, real-time processing, and (b) creating a network that could support the unique needs involved in the exchange of computer-generated data. While an MIT graduate student in 1961, Kleinrock proposed what would later be called "packet-switching" technology, the most efficient way to send data over a network (Kleinrock 1961, 1964). Two other researchers, Donald Davies at the British National Physical Laboratory (NPL) and Paul Baran at the RAND Corporation, were also investigating the idea of packet switching in unrelated research projects in the early 1960s (Baran 1964; Davis, Bartlett, Cantlebury, and Wilkinson 1967). Ultimately, Davies and his group of researchers at NPL would be the first to test a packet-switching network within a building, in Middlesex, England, in 1967 (Zakon 2002).

Packets, Queuing, Demand Access—The Theory of Networking

Packet switching involved chopping messages into packets, assigning each packet a number, sending the packets of data independently through the network, and reassembling the packets at the other end in the proper order in readable form (Hafner and Lyon 1996). The packets could queue up at nodes in the network until they were requested (demand access). In this fashion, network resources could be used as needed and not tied up with open circuits. Researchers hypothesized that packet switching would be a dramatic improvement over circuit-switched telephone networking because it avoided the inefficiency of a continuously open connection. In order to put packet-switching data transfer theory into action, however, ARPANET researchers had to address several key obstacles.

ARPANET planners were well aware that the computers that would be connected to the network were incompatible. Each ARPA-funded site had purchased different mainframe computers from different companies, using different operating systems and different languages (Segaller 1998). Moreover, each site research team was only familiar with the operation of the computer in their respective laboratory. How could these mainframe computers be connected, share data, and communicate with one another with a minimum of errors? Taylor called a meeting of ARPA-funded researchers at the University of Michigan in early 1967 to discuss this and other unresolved network design issues (Anderberg 2002).

Building on an idea proposed by Wesley Clark, a computer scientist at Washington University in St. Louis, the ARPA researchers envisioned a system of smaller, intermediate computers called interface message processors (IMPs) to solve the mainframe-to-mainframe incompatibility problem (Abbate 1999). Each IMP would act as an

Figure 2: The interface message processing design

interface between the network and its mainframe computer (see Figure 2). Every mainframe had to send the same format packets to the IMPs and there was a standard interface all mainframes had to implement. NCP dealt with incompatibilities on an end-to-end basis. Each site's mainframe would communicate with its own IMP, and all IMPs would be designed to communicate with one another using the same operating system and speaking the same language. Roberts distributed a request for quotation (RFQ) to design and build the IMPs in July 1968 and received more than 100 proposals. He awarded the contract to Frank Heart and his team of computer scientists at Bolt, Benerak & Newman (BBN) in Cambridge, Massachusetts, in December 1968 (Anderberg 2002). The final step was deciding which sites would initially be connected to the network. Four sites, each with its own particular research specialties, were chosen: UCLA; the University of California, Santa Barbara (UCSB); Stanford Research Institute; and the University of Utah. The deadline for establishing the network at UCLA was set, somewhat arbitrarily according to Heart, for September 1, 1969, only nine months after the initial proposal was presented. Heart and his group would have \$1 million and less than a year to turn theory into a working system (Hafner and Lyon 1996).

In the summer of 1968, IPTO organized a meeting for graduate students from the universities that would be the first sites connected to the network to discuss the technological aspects of the proposed network. The meeting gave rise to the Network Working Group (NWG), which solidified the collaborative nature of the ARPANET project (Abbate 1999). Rather than one single scientist taking charge of the direction of the group, the attendees recorded their thoughts and deliberations in a set of notes that Steve Crocker soon named request for comment (RFC). Crocker published the first RFC in April 1969, detailing the interface between the hosts and IMPs and asking for input on problems (Crocker 1969). The RFC became firmly established as a means of communicating information and seeking feedback about networking issues, and it was supported by all levels of researchers.

This open manner of sharing ideas in the realm of scientific discovery remains in place to this day and, by many accounts, influenced the eventual spirit of community associated with the modern-day Internet (Internet Society 1999). The entire series of RFCs have been collected and cataloged by Jon Postel, the RFC editor for more than 30 years, and are available for viewing (RFC Editor Homepage, n.d.).

It is important to note that at this point, the number of researchers working on the development of ARPANET was relatively small. In fact, as news of the proposed network spread to scientific circles across the country, the idea was met with little enthusiasm. To the many ARPA-funded research teams, the idea of sharing resources across a network meant that "outsiders" would be meddling in their private computing centers and that their hard-earned computing equipment and power would be depleted. To researchers who still hoped that ARPA would fund their projects, the idea of a network meant that ARPA might not purchase new mainframes for them. Roberts, Taylor, and Licklider tried to win the support of the largely uninterested and skeptical ARPA-funded researchers, eventually resorting to subtle "blackmail" (Segaller 1998), reminding each site that as they were being supported by ARPA with hundreds of thousands, if not millions, of dollars a year, they should be just as enthusiastic about the project as the project managers were. Needless to say, ARPA-funded researchers started to come around, though most doubted the venture would work (Moschovitis, Poole, Schuyler, and Senft 1999).

ARPANET Comes Alive

By early 1969, the researchers at BBN were working around the clock to develop the IMPs by the deadline, whereas the research teams at each university were busy developing the custom software and hardware that would allow communication between their mainframe and the IMP. Significant challenges arose every day, all of which had to be resolved under the pressure of the looming deadline. To everyone's amazement, the UCLA IMP was delivered in time for the September 1 deadline and the IMP-mainframe connection was ready to go a few days later (Zakon 1993). The first test of the packet-switching technology, between the UCLA IMP and its mainframe, was a success. On September 2, 1969, the two machines began talking to each other. The second IMP arrived, at Stanford Research Institute, on schedule one month later and their first official test occurred on October 1, 1969 (Hafner and Lyon 1996).

The plan was to log-on from the UCLA host to the Stanford host by typing "LOG IN." An L was typed at UCLA and Stanford received an L. An O was typed at UCLA and Stanford received an O. A G was attempted and the system crashed. A couple of hours later, however, the system was up and running again, and the researchers successfully logged onto the network, performed some minimal operations, and logged off. The connection between UCLA and Stanford was a success, and the remaining two nodes, one at UCSB, and one at the University of Utah, were working by the end of the year (Zakon 1993). The technology of ARPANET proved that a long-distance packet-switching

computer network was possible. Eventually, the ARPANET helped ARPA cut its computer budget by 30 percent and impressed the skeptics by providing them with more computing power and allowing researchers at different institutes to exchange papers, data, ideas, and software programs and upgrades.

GROWING THE NETWORK

The fifth ARPANET node was installed at BBN in March 1970, and over the next few years, Vint Cerf and Steve Crocker, under Kleinrock at UCLA, and Frank Heart and Bob Kahn, then at BBN, all worked to push the network to the limit, intentionally breaking the network in order to discover weaknesses in the design. They also formed the International Network Working Group in 1972 to coordinate standards. As the number of sites connected to the network steadily grew, moving from the West Coast to the East Coast, new technological innovations kept emerging, some expected and some surprising.

Electronic Mail: The “Killer” Application

In 1971, Ray Tomlinson, a computer engineer at BBN, devised an experimental program, called CPYNET, for sending files between computers. Tomlinson added an additional program to CPYNET for sending and receiving messages, called SNDMSG and READMAIL (Hafner and Lyon 1996). Within a few months, Tomlinson’s application was being used to send messages over the network to machines in different geographical locations. Tomlinson paired each user’s name with the user’s host machine identification using the symbol “@” (meaning “at”), not knowing he was coining the universal symbol of the soon-to-be wired world (Hafner and Lyon 1996). The resulting application, “e-mail” for short, was the first killer application for the emerging network. The network e-mail capability spread rapidly, quickly becoming the most widespread use for the network in the early years. Kleinrock noted that “[a]s soon as e-mail came on, it took over the network. We said, ‘Wow, that’s interesting.’ We should have noticed there was something going on here. There was a social phenomenon happening” (Segaller 1998, 105). The original purpose of the network, to share computing resources across distant geographical locations, was surpassed by its use as a communications tool. The instant popularity of e-mail among the scientists came as quite a surprise because the rationale for building the network was to share access to computers, not access to people (Abbate 1999). Other applications were soon developed that facilitated the creation of “virtual” work groups and news groups, firmly establishing the network as a “virtual community” (Moschovitis et al. 1999).

ARPANET Makes Its Public Debut

At this point, the use of ARPANET was almost exclusively confined to the networking branch of the computer science community, and the general public was unaware of the existence of it. Roberts knew that if the network was ever going to be widely adopted, it was time for a demonstration. Kahn and a small group of principle investigators were asked to devise a showcase of network capabilities. In

1972, ARPANET debuted to the public at the International Conference on Computer Communications (ICCC) in Washington, D.C. (Moschovitis et al. 1999). By that time, ARPANET had expanded to 15 nodes with 23 sites.

ARPANET’s debut to computer vendors, university representatives, government officials, scientists from a variety of disciplines, and the press at ICCC was a success. The system crashed only once over the weekend conference, and oddly enough, this gave Kahn and his colleagues the opportunity to show that problems were fixable (Hafner and Lyon 1996). The conference attendees were astonished, curious, and anxious to become a part of the network; the buzz had officially begun. Although access to ARPANET was still under the tight control of ARPA and the U.S. Department of Defense, the demonstration at ICCC ignited curiosity and confidence in other networking projects. The early 1970s proved to be an intense period of network experimentation. Within three years of the first ARPANET transmission over telephone lines, different types of networks using packet-switching technology emerged. ARPANET remained under the control of the Department of Defense; thus, rather than expand the existing ARPANET, new networks were created. Networks that linked computers through radio connections, such as the ALOHAnet at the University of Hawaii, and ones that used satellites to link computers, such as SATnet, were popping up all over the world (Segaller 1998).

A NETWORK OF NETWORKS

The success at the ICCC conference swelled the ranks of computer scientists who were interested in packet-switching networks. But the 1972 conference revealed that there remained a significant obstacle to realizing Licklider’s ultimate vision of “... a ‘thinking center’ that will incorporate the functions of present-day libraries together with anticipated advances in information storage and retrieval and the symbiotic functions.” Although computers within a network could be used for time-sharing electronic communication and the sharing of files, these same options were not possible between networks. That is, a computer scientist working at the University of Utah (ARPANET) could not exchange files with a colleague at the University of Michigan (Merit). In order for the existing computer networks to become connected, there needed to be a new protocol so that computers on different networks could communicate with each other.

Robert Kahn began researching the internetworking problem at ARPA in 1973 (Kahn 1994). In many ways, the problem of inter networking was similar to the earlier problem of making dissimilar computers communicate that had been solved by using the IMPs. That is, each network used a different language to control the packet switching, preventing computers on different networks from being able to communicate with each other. Kahn decided that the network of networks needed an open architecture that would allow for innovation within networks, without requiring existing networks to abandon their software. The problem of connecting networks was solved similarly to the earlier problem of connecting computers in a network. Kahn’s main collaborator, Vinton Cerf, proposed the idea of “gateways” between

the networks that would employ a common language or protocol. These gateways would allow networks to interconnect in much the same way that the IMPs originally allowed computers to interconnect. Thus, Kahn and his team specified a set of four requirements for the inter-network:

Each distinct network would have to stand on its own and no internal changes could be required to any such network to connect it to the Internet. Communications would be on a best effort basis. If a packet didn't make it to the final destination, it would shortly be retransmitted from the source. Black boxes would be used to connect the networks; these would later be called gateways and routers. There would be no information retained by the gateways about the individual flows of packets passing through them, thereby keeping them simple and avoiding complicated adaptation and recovery from various failure modes. There would be no global control at the operations level (Leiner et al. 1994).

A common language was needed to allow computers from different networks to communicate with one another. Network control protocol (NCP), the software used to oversee packet switching on the ARPANET, lacked end-to-end host error control because packets never traveled outside the ARPANET. Outside the United States, the UK National Physical Laboratory developed a standard called X.25, which subsequently garnered widespread acceptance in Europe and Japan. Meanwhile, Cerf and Kahn wrote the transmission control protocol/Internet protocol suite (TCP/IP) to implement the packet-switching process at gateways (Cerf and Kahn 1974). It took four incarnations before the final TCP/IP software was considered ready for deployment. TCP would be responsible for service features involved in the packet-switching process, including flow control and lost packet recovery, whereas the IP was used for the addressing and forwarding of individual packets. Standardized 32-bit IP addresses were assigned to each computer on the Internet; the first 8 bits signified the network and the other 24 bits designated the host on that network. Initially, TCP/IP protocol was used to connect the ARPANET (50 kbps) land lines, the Packet Radio Net (PRNET at 400/100 kbps), and the Packet Satellite Net (SATNET at 64 kbps; Kahn 1994). On January 1, 1983, the ARPANET made the transition from NCP to TCP/IP as the standard protocol for networking on ARPANET. Now, it was possible to interconnect networks and the *Internet* was born.

Standardization of the TCP/IP software led to the development of commercially available gateways and routers for industry workstations, minicomputers, and mainframes. As the number of local area networks (LANs) increased, so did potential engineering incompatibility problems. The Internet Activities Board (IAB) was founded in 1983 to oversee standardization of networks. For example, the IAB designated three network types based on the expansion of network interconnectivity: class A, which were large-scale national networks; class B regional networks; and class C local area networks. With increasing

interconnection came difficulty in locating information on the Internet. IP addresses of all host computers were found in a distributed file called HOSTS.TXT. Eventually, the updating of this file became a bottleneck, so Paul Mockapetris of USC/ISI invented the domain name system (DNS) to alleviate this problem (1983a, 1983b). DNS assigns and tracks easy-to-remember names to IP addresses across the Internet (e.g., purdue.edu).

The ARPANET/MILNET Split

By 1984, the computer architecture in the United States for the Internet was in place, and a number of computer networks, both governmental and commercial, had emerged. Within a few years, there were a number of networks linking geographically proximate universities. Among these networks were the following.

ARPANET (1969)—UCLA, Stanford University, UCBS, University of Utah, BBN, MI T, RAND Corporation, SDC, Harvard University, MIT's Lincoln Laboratory, University of Illinois—Urbana/Champaign, Case Western Reserve University, Carnegie Mellon University, NASA/Ames.

Merit (1969)—University of Michigan, Michigan State University, Wayne State University.

THEORYNET (1977)—University of Wisconsin.

USENET (1979)—Duke University and University of North Carolina.

CSNET (1981)—University of Delaware, Purdue University, University of Wisconsin, RAND Corporation, and BBN.

BITNET (1981)—City University of New York and Yale University.

The expansion of the Internet to broader academic and commercial interests raised concerns about the security of Department of Defense information on the Internet. For that reason, the military component of the Internet was separated from the Internet, resulting in two networks: ARPANET and MILNET (the new military portion of the Internet). Computers on the MILNET would still be able to communicate with computers on the ARPANET, but the architecture was designed such that MILNET could be quickly disconnected from ARPANET in case of a threat of a security breach.

The NSFNet

Perceiving the advantage of the Internet for scientific research, the National Science Foundation (NSF) decided to expand use of the Internet beyond the limited number of computer scientists and defense contractors and make it available to all disciplines for research and education. Dennis Jennings was responsible for the initial decision to use TCP/IP to build a network linking the NSF sponsored super computer sites. In 1986, the NSF brought in Steven Wolff to oversee construction of a new research network (Leiner et al. 1994). Wolff was charged with developing a computer network that would facilitate cooperative research and that would eventually outgrow its need for NSF funding. In order to do this, Wolff created

Figure 3: Exponential growth of Internet hosts

policy designed to encourage broad-based use of the Internet while encouraging the creation of separate, commercial, long-haul networks. The NSF required universities seeking funding for an Internet connection to make connections available to all qualified users on campus. Further, they encouraged growth of regional networks by urging regional networks to seek commercial, nonacademic customers in order to expand use of the networks, take advantage of increased economies of scale, and ultimately lower subscription costs. They also wrote the Acceptable Use Policy, which restricted use of the national NSF network to academic and research work (National Science Foundation 1986). It was believed that denying commercial users access to the national network would encourage creation of nationwide commercial networks. This strategy paid off when commercial Internet long-haul carriers UUNET and PSI opened.

In 1986, the NSF launched the NSFNET backbone, a high-speed (56 kbs) network connection between six supercomputer centers running across the United States. It was built by MCI, IBM, and MERIT (the University of Michigan). The supercomputer centers were at Princeton University, Cornell University, Carnegie-Melon University, the University of Illinois, the University of Colorado, and the University of California, San Diego. In under nine years, the NSFNET backbone grew from 6 nodes at 56 kbs to 21 nodes at 45 mbs, connecting 50,000 networks on all seven continents and in space.

FINDING OURSELVES IN VIRTUAL SPACE

A network with the breadth and reach of the Internet quickly surpassed users' ability to keep track of the location of information. With 50,000 networks, keeping track of files and IP addresses quickly became impossible. Soon computer scientists began writing software to help users find and transfer files. One of the most popular was Gopher, released in 1991 by Paul Lindner and Mark P. McCahill from the University of Minnesota. Gopher, and its descendents, allowed users to search through "Gopher space" for files to transfer via file transfer protocol (FTP). Gopher was an Internet protocol that provided

menu-driven file-and-data retrieval from remote computer servers (Anklesaria et al. 1993). Gopher sites organized files for retrieval and were set up to be searched by users. Although they were text-based, these early versions of Internet searching software greatly simplified the problem of finding files on the Internet.

All this was soon to change. Desktop computers were becoming easier to use because of graphical user interfaces, developed at the Xerox Palo Alto Research Center (PARC), and the commercially distributed Apple Macintosh operating system, in 1984. One year after the introduction of the Macintosh operating system, Microsoft released the Windows 1.0 operating system in an attempt to replace MS-DOS text commands with an intuitive point-and-click graphical user interface similar to the Macintosh operating system, although the Windows operating system would not become commercially popular until the introduction of version 3.0 in 1990 (Microsoft 2002). Computing power that the early Internet pioneers could only dream of had found its way to business desktops, elementary school classrooms, and home recreation rooms. Access to the Internet was increasingly supplied to the general public through commercial gateways and public access points, such as Michigan's Merit network and Cleveland's Freenet. The number of hosts on the Internet had grown exponentially through the 1980s (see Figure 3). But the biggest change in the Internet was still to arrive.

The World Wide Web

In the late 1980s, Tim Berners-Lee was a research fellow at the European Laboratory for Particle Physics (CERN) in Switzerland. He had become intrigued with using computers to organize information via hyperlinked connections. As his ideas developed, his vision fixed on a scalable system for linking related documents via the Internet. It was important that such a system not use a central database to keep track of files, as updating the database would limit its speed and size to available resources (because of computer storage limits and the human resources needed for updating the database). Instead, Berners-Lee wanted all system users to be able to both find and contribute

information. Administrators at CERN had a difficult time understanding what use they could make of Berners-Lee's invention and would not provide financial support for him to pursue the idea. Nonetheless, he persevered and finally received financial support in the form of a new NeXT computer.

Steve Jobs was forced out of Apple in 1985 and started up NeXT computers. Jobs felt his computers were the "next" great advance after the Macintosh for desktop computers. Berners-Lee found that much of what he needed to create his World Wide Web hyperlinking software was available on his NeXT computer. He developed an early prototype Web browser to make the CERN phone directory available online. From this modest success, he continued to promote the use of the Web both inside and outside of CERN. He traveled to the United States to display the Web at a conference of hypertext developers, posted information about the Web on Internet user groups, and provided telnet access to the browser on a server at CERN so that people could try it out.

Berners-Lee's (1999) vision was that the Web would maximize flexibility while accommodating standards that were already in play on the Internet. He wanted the Web to be open to existing Internet protocols, so he designed it to read FTP, Gopher, network news (NNTP), wide area information server (WAIS), and other documents. This was accomplished, in part, by specifying the protocol at the beginning of the link address or uniform resource indicator (URI). For example, links to FTP files began with "ftp://...", whereas links to Gopher sites began "gopher://...". His own protocol for linking hypertext documents is the now familiar hypertext transfer protocol (HTTP). This software provided instructions on how to download and connect hypertext documents via the Internet. Finally, Berners-Lee standardized the language that Web page designers would use, based on the earlier text and database publishing language SGML, called hypertext markup language (HTML).

The First Browsers and the Rise of Popular Internet

Despite the obvious advantages of the Web, which we see in retrospect, few in the computing world were eager to adopt this new technology (Berners-Lee 1999). Although Web browsers were developed for operating systems commonly used by computer programmers (e.g., UNIX), they were not available for the most commercially popular operating systems (PC, Mac), and Web editors were even more rare. Without a browser that was easy to install and without abundant content to discover, the Web was unlikely to take off. In 1993, Marc Andreessen and colleagues at the University of Illinois National Center for Supercomputing Applications (NCSA) released Mosaic, a Web browser that was eventually available for UNIX, Macintosh, and PC. The immediate advantage of Mosaic was that it was graphical, user friendly, and easy to install. Mosaic caught on quickly, thanks in part to an aggressive public relations campaign by the University of Illinois. Web use increased at a rate of over 340,000 percent in the first year. Soon new technologies proliferated on the Web. By the end of 1995, real-time audio streaming was

made available by RealAudio, RT-FM had begun netcasting from Las Vegas, the Arizona law firm Canter & Siegel introduced "spam" to the Internet by mass e-mailing of advertising for immigration services, banner ads were introduced, Sun Microsystems introduced JAVA, and virtual reality markup language (VRML) made its appearance on the Web.

In 1994, Mark Andreessen left the NCSA to form Netscape Communications with Jim Clark. Netscape soon produced its own version of the Mosaic browser, making it available for free to educational institutions and for a small fee to others wanting to use the Web. Microsoft was slow to realize the potential of the Web but aggressively joined the Web when Bill Gates decided to bundle a Web browser with the new release of Windows 95. Rather than write their own code, Microsoft bought the rights to a NCSA spin-off browser from a small company called Spyglass for \$2 million (Berners-Lee 1999). This marked the beginning of what became known as the "browser wars" between Netscape and Microsoft. Sensing competition in the market that it thought it controlled, Netscape urged the Justice Department to pursue antitrust action against Microsoft for bundling its browser with the most popular desktop operating system. Although this case, *US v. Microsoft*, demonstrated that Microsoft did use its market power to drive competitors out of the market, the settlement did nothing to relieve the harm done to the market. Netscape was forced out of business and was bought out by AOL. In protest of the decision, nine states and the District of Columbia withdrew from the case settlement stating that it was little more than a slap on the wrist.

In the years following 1995, the Internet, World Wide Web, and related technologies grew in the public consciousness. Magazines, newspapers, and television programs increased coverage of this new technology. Debates erupted on Capitol Hill in Washington, D.C., about what content could be allowed on the Web. Maybe most important for the continued development and commercialization of the Internet, Congress passed the Telecommunication Act of 1996, opening up media and telecommunications companies to increased competition. People became troubled by such security issues as "hacks" and "viruses" even as they slowly began purchasing products from "e-tail" outlets, such as Amazon.com, and auctions sites, such as eBay.com.

Google: A Web Necessity

As Web use expanded through the second half of the 1990s, it became necessary to have an application that would allow the user to more efficiently search for information. A number of companies offered search engines based on a variety of search strategies. Some early search engines required Web site administrators to register their site with the search engine, while others worked on algorithms to locate key search terms on Web sites. Out of the fray emerged the most popular and powerful search engine to date: Google. The advantage that Google offers users is that it calculated site importance based on the number of other sites that are linked to it. Thus, a Google search typically finds the most informative and pertinent Web sites—in relative rank order—for any search term.

Launched by two Stanford graduates in 1998, Google (which borrows its name from the mathematical term “googol,” defined as a numeral one followed by 100 zeroes) quickly became most popular search engine, currently registering over 91 million unique searches per day (Search-EngineWatch 2006). The growing popularity of the Google search engine attracted many investors, and on August, 19, 2004, the company went public. By the end of the first day of trading, Google had received more than \$1.67 billion, making it the largest initial public offering (IPO) in financial history.

Updates to Google allow users to track down images, newsgroups, news stories, items for sale, and directions and maps of most anywhere in the world via satellite imagery. In addition, two new Google programs—Gmail and Google Desktop—have been launched by Google that allow users to search their e-mail files and hard drives using Google’s patented search technology. Recently, Google acquired the popular YouTube video delivery service. All of these features and programs are available to users at no cost.

However, Google has not been free of criticism. The Gmail program has been targeted by information privacy activists who are concerned because the program attaches customized advertisements to users’ message when they are sent. For example, if one college student were to send a party invitation to another student and mentioned “beer” in the message, Google would attach a beer advertisement to the message. Copyright attorneys have repeatedly claimed that Google’s search program makes it far too easy for individuals to steal images, text, and other proprietary information. Google’s method of ranking search results has also been criticized, as it allows for corporations to purchase “paid-return” links, which will return specific links whenever a specific search term is entered. In a recent debate over electric cars, General Motors Company paid Google to include links to its Web site to combat negative publicity it was receiving from another Web site’s blasting of GM’s alleged anti-alternative energy policy; this type of paid-search return bothers many Web neutrality supporters who worry that this practice limits information sources to users.

The Semantic Web

Although Google is currently the most popular engine for navigating billions of Web pages available to the general public, it is still not the “gold standard” envisioned by Web pioneer Tim Berners-Lee. Berners-Lee and others at the World Wide Web Consortium continue to develop a more sophisticated mechanism for finding information on the Internet that allows machines to retrieve information based on semantic meaning. Sites on the semantic Web will have descriptive data included that will allow machines to read the meaning of information on the page. Included in this system are the resource description framework (RDF) that specifies information in a subject-predicate-object semantic expression, the Web ontology language (OWL) that provides additional vocabulary for describing properties and classes of information, and a new mark-up language called XML that provides the data descriptions used by RDF and OWL. Among other things, the semantic Web will allow

computers to “talk to” each other, essentially creating a Web-based on machine intelligence in addition to human intelligence. Time-consuming tasks will be taken care of by computer agents on behalf of humans.

Web 2.0—The Present and Future of Activity on the Internet

Collectively, the browser wars, Google, and the semantic Web represent the events defining the core transition from the Internet of the past to the Internet of the future. The origins of the Internet were rooted in information-sharing and communication, with an emphasis on designing and selling applications, such as a Web browser. Some see the future of the Internet relying on delivery of powerful services, and providing the conduit through which information can be shared (e.g., peer-to-peer networks, wikis, and personal blog sites) and found (e.g., Google). This vision of the Internet has been dubbed Web 2.0.

The idea of Web 2.0 has been most enthusiastically advanced in a series of conferences hosted by computer science book publisher O-Reilly Media. Web 2.0 is envisioned as a qualitative shift to a new type of Web that attempts to leverage the collective intelligence of Internet users (Kelly 2005). This is accomplished via an impressive array of new activities one can engage in on the Web. Importantly, users provide the intellectual content; Internet companies provide access to and archiving of the enormous database that emerges. Unlike traditional media companies, new Internet companies won’t necessarily require content experts as users provide much of the content.

One of the more impressive examples of user provided content has been Wikipedia. Launched in 2001 and based on wiki technology that allows users to add, remove, and edit content, Wikipedia has evolved into a large, decentralized and free online encyclopedia consisting of submissions and edits by Web users. Wikipedia claims to have over 5 million entries and is published in 250 languages. Alexa estimates that Wikipedia receives 55,000 hits per day, putting it in the top 20 most popular sites on the Web.

Currently, the most popular site on the Internet is another example of Web 2.0, MySpace. According to Hitwise (www.hitwise.com), MySpace accounts for 4.63 percent of Internet market share. MySpace began in 2003 as a social networking site modeled after friendster.com. It provides free searchable space for users to post photos, music files, and blogs, in addition to joining content-based groups. Importantly, sites on the service are networked by invitation, creating a massive collection of networked user-provided information. Portrayed as another hacker inspired Internet success story, MySpace is the actually the brainchild of viral marketing agent InterMix Media and is owned by Rupert Murdoch’s News Corp.

Not all Web 2.0 have met with such wide acceptance. In 1999, college student Shawn Fanning released a simple application that allowed friends to share larger files more efficiently across the Internet. This application, Napster, was intended to be used to share MP3 music files among friends. However, soon the technology allowed for

searching for MP3 files and the music industry, feeling its copyrights were under threat, fought to kill the service. Though successful in killing Napster, the industry hasn't been successful in killing off new versions of peer-to-peer sharing networks. Decentralized peer-sharing software, such as LimeWire, allow users to download free file-sharing software that gives them access to files and programs on other registered users' machines (LimeWire 2006). The legality of sharing copyrighted information via the Internet has been challenged, but these programs still remain popular with Internet users. Although service providers such as LimeWire have been held harmless from civil lawsuits brought on by copyright holders (it has been established that file-sharing network providers are not responsible for the information contained on their public-access networks), individuals who illegally download copyrighted files and programs have been successfully prosecuted.

Internet and Media Convergence

Web 2.0 has not replaced traditional media content providers. Nearly every major news media outlet has a registered Web page that is updated throughout the day. Some news media sites offer exclusive content online that is not offered in the print or televised edition, and a select few no longer produce print or televised versions. For example, the Web site for *The New York Times*, the most popular print newspaper in America with a daily readership of nearly 5 million, registers nearly 1.1 million daily hits; in addition, the newspaper sends out over 3.3 million news alerts to registered users each day (New York Times 2005). Similar to the news media, several leading radio shows and cable stations, such as The Howard Stern Show (www.howardstern.com) and Comedy Central TV (www.comedycentral.com), now offer their content via the Internet, in addition to posting Web-exclusive content for registered users. Video games have taken advantage of this as well. Gamers can log on and play in each other in games ranging from chess and dominoes to Dungeons and Dragons simulators. Gambling and betting has also become a popular use of the Internet, especially for those users who don't live in areas where casinos are located or permitted. Some estimates claim that over \$15 billion is wagered annually in online casinos, many of which are illegally registered (Lemke 2006).

Colleges and universities, traditional information providers, have started offering online classes to students. Community colleges and trade schools have also tapped into this growing trend, and some institutions, including the University of Phoenix (www.universityofphoenix-online.com) offer complete degree programs, including some graduate degrees, without ever requiring a visit to a college campus. Many of these programs cater to working adults and other "non-traditional" students who often don't have time to attend regular college classes.

A different type of information, product information, has become very popular on the Internet. E-commerce is a boon to today's economy, with billions of dollars in transactions annually on goods and services ranging from pizza delivery to an original Picasso (Pascale 2000). Just as many media outlets have included the Internet

for part or all of their daily coverage and leading businesses now offer their goods and services for sale online. Research by the Boston Consulting Group showed that, by the end of 1999, online spending accounted for more than \$44 billion (Pascale 2000). This trend was not lost on the mainstream retailers. In January 2000, Wal-Mart launched www.wal-mart.com, which offers over 1 million items for sale that can also be found on the shelves of their 5,000-plus store locations worldwide. And eBay, a popular auction house that allows users to buy and trade their personal items online similar to a virtual swap meet or garage sale, reports that over \$15 billion annually is transacted on their site between some 42 million registered users (see <http://pages.ebay.com/aboutebay.html>).

From Personal Information to Personification

For a growing number of 'Net surfers, personal blogs and Web pages simply aren't personal enough. As technology improves, it is now possible for people to create personal characters, or avatars, that occupy virtual "worlds" in a three-dimensional, fully-interactive environment. Popular video game developer Blizzard Entertainment, owners of the Warcraft franchise, have capitalized on this phenomenon in their World of Warcraft game. This game, one of the first massively multiplayer online role-playing games (MMORPGs), boasts over 5 million active players from across the globe who pay a monthly subscription rate, typically around \$30 per month, to live in the virtual land of Azeroth and accept the trials and tribulations that come with being a member of the warring factions of Hordes and Alliances (Blizzard 2006).

For users wanting a more "realistic" online living experience, Second Life (www.secondlife.com) offers residents a chance to buy property and live in a world that includes virtual shopping malls, space stations, vampire castles and movie theaters, among other "worldly" amenities. Unlike World of Warcraft, where the focus of the game is primarily challenge and competition, Second Life encourages users to adopt and experiment with an entirely new existence. As of 2006, the site boasts over 175,000 full-time residents who spend over \$150,000 US, or \$3.75 million Linden Dollars (the official currency of Second Life) daily on everything from virtual land and clothes to other users' characters. And the incentives for living online are appealing; allowances for basic account holders start at \$50 Linden Dollars per week and increase with play time, and players who start virtual businesses and host virtual parties and events are rewarded with cash prizes, both in virtual and real dollars (Linden Labs 2006). To date, companies including Adidas, Reebok, Toyota, Nissan, IBM and Starwood Hotels have taken up residence in the Second Life world. Additionally, the news service Reuters has even opened a news bureau in Second Life.

A DIGITAL DIVIDE

As the Internet became more prevalent, an increasing number of public officials in the United States worried that a substantial portion of the population was being

denied access to this newest form of telecommunication. In the mid-1990s, the U.S. Department of Commerce was concerned that this new technology was not achieving the goal of “universal service” that is the core of U.S. telecommunications policy (Department of Commerce 1995). In response to this perceived inequity, the Department of Commerce, in conjunction with the National Telecommunications and Information Administration, commissioned a series of reports to investigate the source of the problem. Their first report, released in July 1995, found that the rural poor—those living under the poverty line and away from urban centers—were at a significant “information disadvantage,” as only 4.5 percent of these households had a computer, and less than 25 percent of these computers had the technology required for Internet access (i.e., modems and Web browsers). At the same time, urban poor were not doing much better, as less than 8 percent of these people had computers, about 45 percent of which had technology capable of accessing the Internet. Similar divides were found across age and education levels. These findings led to a series of reports on the newly discovered digital divide that appeared to separate the information “haves” from the information “have-nots.”

A second report, released in July 1998, showed a significant nationwide increase in Internet access capability (i.e., households owning a computer with a modem). However, the report also identified the same pockets of “have-nots” as the first report, and policy discussions shifted to identifying why these people were still not connected. In November 1999, a third study released by the NTIA identified a promising trend: over one-third of all Americans were now connected to the Internet. For those people who did not have Internet access in the home, they were finding it easier to gain access by using public schools, libraries, and other community access centers. Also, their Internet usage was less recreational than the “haves,” as they frequently used the Internet to enroll in college courses or to search for jobs.

By October 2000, a fourth study released by the NTIA showed that nearly 42 percent of Americans were logging onto the Internet, and the “have-nots” were experiencing the highest expansion and growth rates across all identified populations. Although an access gap still existed, the focus of the research had begun to shift to a more positive trend of identifying “digital inclusion” rates rather than a digital divide (Department of Commerce 2000). The final report of the NTIA, released February 2002, found that over 50 percent of the population readily identified as consistent Internet users, and that over 2 million new users sign on to the Internet every month (Department of Commerce 2002). An excerpt from the final page of the report proclaims:

Our nation has passed a significant milestone now that the majority of Americans use computers and the Internet for their daily activities. This trend is enriching our world, facilitating our work lives, and providing a skill set needed for a growing economy.

Worldwide, the numbers are quite different. Currently, Internet use around the world is only at 16 percent penetration.

The lowest penetration rates are in the most populated continents: Asia, representing 56 percent of the world's population, has an Internet penetration rate of only 11 percent. The second largest continent by population, Africa, is home to 14 percent of the world's population, but has an Internet penetration rate of only 4 percent. Compare these rates to Europe (12 percent of world population) and North America (5 percent of world population), which have 32 percent and 69 percent penetration respectively. Although the divide has reduced significantly in some areas of the world, the problem still remains a global issue.

Anybody's 'Net?

Positive trends in U.S. adoption of the Internet may point to issues that still need attention in developing nations. Data from the Pew Internet and American Life Project (2006) estimates that over 147 million U.S. citizens are now online; a number representing over 73 percent of the U.S. population. The report identified three factors that led to the shrinking divide in the United States.

1. Lower cost of access: In the mid-1990s, access to the Internet was not affordable to the average American. Internet Service Providers (ISPs) charged anywhere from \$20 to \$60 per month for subscription-based Internet access, which usually limited Web usage to a few dozen hours per month. Connection speeds were very slow, ranging between 9.6 and 14.4 kilobits per second (keep in mind that a one-page Microsoft Word text-only document is about 23 kb in size) and these connections were often unreliable. Today, a faster, more reliable Internet connection can be installed at home starting at \$6.95 per month for unlimited high-speed access.
2. Less computer knowledge required: Establishing Internet access in the mid-1990s could be difficult for the computer novice, as a working knowledge of networking jargon (e.g., TCP/IP protocol, modem settings, installing additional hardware) was necessary before one could surf the 'Net from home. Often, the monetary and opportunity costs of getting connected were too much for the average person, slowing diffusion (Rogers 2004). The process is much easier today, as ISPs routinely provide software free of charge to new subscribers and connecting the hardware is usually as simple as plugging a color-coded Ethernet or phone cable into the back of your machine and starting the appropriate Web browser program.
3. The Internet has become ubiquitous: Many advertisements in the United States refer the audience to a Web address for more information. Business associates and even men and women on the dating circuit often exchange their e-mail addresses along with (and sometimes in place of) phone numbers. As well, entire businesses, organizations, and communities exist wholly within cyberspace. There is a general assumption and understanding that the Internet is always there, and is readily accessible to meet our diverse information and entertainment needs.

CONCLUSION

The precursors of the Internet have outlived their usefulness. The ARPANET shut down in 1990 and the original NSFNET backbone followed in 1995. The NSF created the vBNS (very high performance backbone network service) through MCI in 1994 and it was used to link supercomputer centers sponsored by NSF. Nonetheless, there remains a place on the Internet restricted from trade and dedicated to researching and developing new communication technologies. Internet2, the very-high-speed backbone network, was created in 1996 and limited to research only. Internet2 is a project of the University Consortium for Advanced Internet Development (UCAID) and it uses both the vBNS network and the Abilene Network from QWEST to achieve desired flexibility. Internet2 continues to expand the horizons of new technologies, introducing richer communication experiences via three-dimensional immersive environments.

The Internet was born of the excitement of solving complex engineering problems in an open and collaborative manner. This led to an open-architecture design that has been flexible enough to support exponential growth in hosts and users as well as technological innovation in software. With a minimum of governance, the Internet has grown to be the information infrastructure for the twenty-first century, supporting the exchange of audio and video files, animations such as Shockwave Flash, three-dimensional interfaces such as VRML, media wrappers such as QuickTime, chat rooms, and instant messaging. Web 2.0 offers the vision of new user participation on the content end.

As the Internet has become more inclusive, it has grown to reflect the interests and ideas of a broad spectrum of people around the world. Despite tremendous expansion, it remains a forum for the exchange of ideas and information; what has changed is who is exchanging ideas. Truly an egalitarian forum, the Internet has expanded well beyond the technical details of engineers and scientists into the art and introspections of a great variety of people around the world. It is difficult to imagine where innovations on the Internet will take us, but it is clear we will never see the Internet in its final form. If future designers adhere to the simple rules of the Internet pioneers—an open architecture built through cooperation—we will likely never see the Internet stop evolving.

GLOSSARY

Advanced Research Projects Agency Network (ARPANET): Created by the U.S. Advanced Research Agency (ARPA) in 1969. ARPANET was a wide area network linking computers at various university research centers. ARPANET is considered the precursor to the modern-day Internet.

Analog: Electronic transmissions that represent data by continuous signals of varying frequency (versus being sent as an “on or off” data transmission; see *Digital*).

Circuit switching: A communication technology in which a dedicated path is established between the source and destination for the duration of the transmission. The telephone network is an example of a circuit-switching network.

Digital: Electronic transmissions that represent data in various combinations or strings of 1’s and 0’s, with 1 representing “on,” or “positive, and 0 representing “off,” or “nonpositive.”

Host: A computer system containing data that is accessed by a user at a remote location.

Interface message processors (IMP): Smaller, intermediate computers connected to the mainframes involved in ARPANET. The IMPs were packet switches dedicated to the communications “subnet.”

Internet: A vast system of linked computer networks, international in scope, that facilitates data transfer and communication services, such as remote log-in, file transfer (FTP), electronic mail (e-mail), newsgroups, and the World Wide Web (www); always capitalized.

Intranet: Internal network utilized within organizations allowing file sharing and collaboration. Intranets cannot (generally) be accessed from outside the organization.

IP address: A numeric address that identifies host computers on the Internet.

Local area network (LAN): A network that connects computers in a relatively small geographical area (generally no more than 2 miles). LANs are used in offices, buildings, or a set of buildings.

Network: A collection of two or more computers (and/or printers, routers, switches, or other devices) connected to one another allowing data to be shared and used over communication paths.

Network control protocol: The host-to-host protocol of the ARPANET that operated above the layer of packet switching implemented in the IMPs. Once ARPANET transitioned from NCP to TCP/IP, it was possible to connect to other independent networks.

Node: A connection point in a network, either for redistribution of data or as an end point for data transmissions.

Packet switching: Method used to efficiently move data around on a network. Data is divided into smaller pieces called packets, assigned a number and destination, sent independently through the network, and reassembled at the other end.

Protocol: Formal set of rules that govern how devices on a network exchange information; the “language” of a network.

Request for comment (RFC): Document series used among researchers as the primary means of communicating ideas and information about the Internet.

Router: The device that forwards packets between networks.

Transmission control protocol/Internet protocol (TCP/IP): The common language that allows existing networks to be connected, or “inter-networked.” TCP implements flow control and recovery in packet switching, and IP is used for addressing and forwarding individual packets. TCP runs over IP and the two form part of a layered protocol stack.

Uniform resource locator (URL): A character string describing the location and access method of a resource on the Internet.

World Wide Web: Invented in 1991 by Tim Berners-Lee, the World Wide Web is an application that facilitates

exchange of documents via the Internet. It uses a variety of protocols including: HTTP, HTML, FTP, VRML, XML, and SSL.

INTRODUCTION

The Internet2 project was established in 1996 by a consortium of universities, corporations, and government agencies to support a variety of academic innovations requiring advanced networking capabilities. Currently, more than 200 universities, 60 corporations, and 40 affiliate members compose this "invitation-only" initiative, which serves an estimated 5 to 10 million people.

The mission of Internet2 is to improve scholarship and serve the needs of academics in universities, colleges, and schools with cutting-edge data processing solutions. The goals of the Internet2 consortium are to create a leading edge network capability for the national research community, to enable the development of revolutionary Internet applications, and to ensure the rapid transfer of new network services and applications to the broader Internet community. This next generation Internet promises to do what academics and researchers hoped the first generation Internet would do; that is, allow scholars to make use of its potential to collaborate with colleagues, researchers, and students around the world across a secure, uncongested, high-speed network.

SHORT HISTORY OF THE INTERNET

Origins

Rooted in the military culture of the cold war, the Internet's original ancestor was established at the Advanced Research Projects Agency (ARPA) of the U.S. Department of Defense. It was called ARPANET and was created out of the need for a robust, redundant system capable of carrying critical military data throughout a relatively small network of then-powerful computers. Serving as a critical element of military preparedness and civil defense, ARPANET was designed to function regardless of any kind of network disruption, no matter how cataclysmic. The original ARPANET has been replaced by a succession of bigger, faster, more powerful networked systems, leading

to today's Internet. Sensing the potential of distributed computing for science discovery and application, the National Science Foundation (NSF) created a network dedicated to academic research and development based on the ARPANET's Internet protocol. Operating from a system of regional computing systems interwoven by an Internet "backbone," the Internet offered researchers immediate access to colleagues and files throughout the world.

The Internet has grown into a loose amalgam of individual networks and computer systems, all operating according to agreed-upon network protocols allowing the worldwide transfer of information among systems built on a variety of operating platforms. As distinct from many of the well known commercial online network service providers (e.g., *America Online*, *AT&T Worldnet*), no individual, company, agency, or institution owns the Internet. It is a distributed system of interconnected computers and networks. This means that no single hyper computer or super network drives it. Rather, it is an enormous, electronic global neighborhood where some houses are bigger and more luxurious than others, but each one arranges its own furniture and landscaping.

The Internet's origin may be traced back to an American sense of shock and fear caused by the 1957 launch of Russia's first-ever space orbiting satellite, Sputnik. The earliest Internet-type operation was launched in 1969. At the time, this network was composed of four hosts (UCLA, Stanford, UC San Bernardino, and the University of Utah). By 1982, the Internet had grown to more than 200 hosts. By 1995, there were almost 6 million hosts, and at the end of 2005, the number had grown to more than 353 million.

Over 200 countries are now connected to the Internet (post-Taliban Afghanistan has recently become connected.) When we add other networks capable of interfacing with the Internet in some manner or other, the number of nations increases still further. As of December 2005, Zakon (2005) placed the number of Web servers at more than 70 million. Because most servers host multiple

Table 1: Internet Timeline

Year	Event
1957	First orbiting space satellite, Sputnik, launched by the former USSR
1963	First dial-up modem developed
1969	Four-node ARPANET established with network speed of 50 kbps
1972	First e-mail message sent using the @ sign; first computer chat undertaken
1976	First Internet routers developed; Queen Elizabeth II sends e-mail
1977	First Transport Control Protocol (TCP) developed
1979	Emoticons “;-)” first appear in e-mail messages as antidote to dry text
1980	Accidental virus brings ARPANET temporarily to a halt
1982	TCP/IP protocol established as technical standard to drive Internet traffic
Mid-80s	Loose coalition of networks in ARPANET becomes known as Internet
1988	“Worm” infects 10 percent of all Internet hosts
1989	Creation of interconnected regional academic networks
1990	ARPANET decommissioned, leaving a loose network of networks, the Internet
1991	World Wide Web and Gopher are launched
1992	First Internet audio and video transmissions
1993	MOSAIC, the first GUI Web browser released; White House comes online
1994	First banner ads appear on the Web; first pizza ordered online
1995	Real-time audio streaming technology launched; Radio Hong Kong hits the Internet
1996	Internet becomes truly global; US Communications Decency Act (CDA) passed
1997	CDA ruled unconstitutional; Microsoft challenges Netscape with MSIE browser
1998	US Postal Service sells stamps for downloading and printing from the Web
1999	Securities fraud on Web raises a small company’s stock price by 31percent in one day
2000	Catastrophic “denial of service” attacks launched against Amazon, eBay, and Yahoo
2001	Napster forced to suspend free service; resumes shakily as a subscription service
2002	Internet boasts more than 147,000,000 hosts (727,000 in 1992; 235 in 1982)
2003	Apple Computer introduces Apple iTunes music store; sells songs for .99 cents each
2004	Network Solutions begins offering 100 year domain registration
2005	“Podcast” is Word of the Year

Web sites, the number of sites would be in the hundreds of millions.

Some noteworthy Internet benchmarks are illustrated in Table 1.

With such growth has come a change in purpose and tone. In its earliest incarnation, the primary Internet purpose was military. As the Internet moved beyond military use, its function shifted to research and scholarship. At the dawn of the 1990s, the Web had neither entered the national lay consciousness nor had it become viable for commercial transaction. The 1990s changed all of that. In the industrially developed world, the Internet became an indispensable tool for all kinds of business, serving

vendors, and consumers alike. As a result, the charitable camaraderie that characterized a relatively small number of Web users in the early 1990s has now become primarily a commercial marketplace, in which transactions for information, misinformation, financial services, transportation, products, education, romance, entertainment, culture, hate, and pornography are routinely carried out. From an earlier culture of open information sharing, a more defensive posture to protect commercial and personal interests has emerged. By the year 2000, the old neighborhood had changed for good.

With this change has appeared the ever-growing danger of mischief, intellectual property theft, and malicious

destruction. Ever more devastating computer viruses and worms spring up faster than updated virus protection software can thwart them. Major institutional networks have been disabled for days at a time and sometimes longer by viruses such as *Melissa* (1999), *Love Letter* (2000), *Nimda* and *Code Red* (2001), *SQL Slammer* (2003), and *Kama Sutra* (2006). Network hackers have broken into the presumably secure private networks of major corporations (e.g., Microsoft), transportation services (e.g., British Rail), and the governments of several nations (e.g., the U.S. Senate). Predators have harmed children. Meanwhile, a passionate debate rages between those who advocate for legal restraints on putatively harmful Internet exploitation and those who value intellectual freedom above everything.

Globalization

Although a worldwide affiliation of groups vocally oppose economic and cultural globalization, Internet-based e-commerce has not only made common business transactions more accessible to global markets but has also created exponentially richer international choices in education, entertainment, and culture. For example, classical music buffs may choose from nearly 100 radio stations worldwide, many of them uninterrupted by annoying commercials. Such a shift in the network zeitgeist has created many employment opportunities and threatened others (e.g., travel agents). The Internet domain naming system, at one time limited to only six categories (.com, .edu, .gov, .mil, .net, and .org) has added several categories to accommodate growth (e.g., .biz, .info, .name, .us, .tv, .museum and .aero). Partly because of the inchoate spawning of commercial traffic, Internet2 represents an effort to regain the prominent place for research and education that formerly dominated the original Internet.

THE TRANSFORMATION: INTERNET TO INTERNET2®

The introduction of graphical user interface browsers forever changed the face of the Internet. Rather than a medium used only by those who understood how to navigate a text only protocol, the Internet became accessible to anyone who could operate a mouse and a keyboard thus creating congestion on a network that was not originally developed to handle this type of traffic.

Solutions to these network traffic problems, much like solutions to highway traffic problems, continue to be inadequate. At the same time that colleges and universities are trying to speed up and protect the delivery of data via the Internet with the addition of T1 and T3 lines, the demand for additional bandwidth has increased. The need to speed up the delivery of information has led to the creation of a new Internet protocol, IPv6 or Internet protocol version 6, which is currently being promoted and coordinated by the Internet2 IPv6 Working Group. IPv6 allows files to be transported as one packet to many locations and promotes the collaborative participation envisioned by the original designers of the Internet. High-capacity and high-speed delivery of data can be achieved once universities join the members-only Internet2 consortium.

THE INTERNET2® CONSORTIUM

This new generation high-speed network has been developed by the Internet2 consortium, which is a nonprofit research and development consortium that is currently led by over 200 universities in the United States. Member universities work in partnership with industry and government organizations to develop and deploy advanced Internet applications and technology (Internet2 2005a). The Internet2 consortium is governed by a board of trustees primarily composed of the presidents of the Internet2 university members. This board of trustees also governs the University Corporation for Advanced Internet Development (UCAID), which is the formal nonprofit organization that was formed to manage the activities, programs, dues, expenditures of Internet2.

The Vision

The essence of this new generation of network-based applications is to recreate the mission of the first generation Internet; that is, use advanced technology to support a variety of academic innovations that are designed to improve scholarship and allow for collaboration among colleagues and students around the world while serving the needs of academics in universities, colleges, and schools that require cutting-edge data processing solutions.

There is no doubt that the Internet has impacted teaching, learning, and research in a very important way. Interaction between faculty and students using online communication and course management tools have engaged students in learning experiences beyond the walls of the classroom. The Internet also provides the accessibility of online library materials any time of the day or night from computers located in coffee shops, airports, homes, and workplaces. Even while these advances are significant, Internet2 visionaries suggest that a new generation of network-based applications necessitates the need to build a unique environment that "will engender new possibilities for the synthesis of ideas that can ultimately lead to the creation of important new knowledge" (Wasley 1996). The current generation Internet cannot accommodate these needs.

Developing Tomorrow's Internet

Contrary to the unfettered growth of the first generation Internet, growth of the Internet2 has been controlled. Douglas E. Van Houweling, the current president and CEO of Internet2 works with a core staff of individuals who support the work of Internet2 members, overseeing three critical areas: 1) member and partner relations, 2) technology direction and development, and 3) deployment and infrastructure delivery. Their mission is to develop and deploy advanced network applications and technologies and then to transfer these new developments to the broader educational and network communities to create what is being called "tomorrow's Internet" (Internet2 2005a). Some of these new technologies such as IPv6, multicasting, and quality of service (QoS) will help to create a foundation upon which revolutionary network applications can be created. Completely new applications such as digital libraries, virtual laboratories,

distance-independent learning and tele-immersion, inconceivable on the commodity Internet, have become a reality on the high-speed and high-capacity network associated with Internet2 (Internet2 2005d). Long-term, the goals of Internet2 are to accelerate the transfer and diffusion of these new developments into the commercial and public sectors, including K-12 educational environments and public libraries with a “focus on providing Internet2 capabilities to people with vision who have ideas how to use the network” (Van Houweling 2006).

The Partners

At the core of Internet2 collaborations are the partnerships. The partnerships between academia, industry, government and international organizations that existed when today's Internet was being created are being recreated to help develop and deploy Internet2 advanced networking technologies (Internet2 2005f). It is because of the close collaborations between Internet2 partners that research and development initiatives have been made possible.

Internet2 Government Partners

The United States government provides important support for Internet2 projects and initiatives. Internet2 and various United States government agencies have forged connections on many levels; however, the main role of Internet2 government partners has been to support innovation at the principal investigator or institutional level. The federal government also supports the link between Abilene and Internet2 international partners. Many federal agencies such as the National Science Foundation, United States Census Bureau, National Institutes of Health, the National Aeronautics and Space Administration, the National Oceanic and Atmospheric Administration, and the Library of Congress are Internet2 Affiliate members. Many Internet2 member universities work in partnerships with federal agencies to research new Internet technologies, and Internet2 is a key collaborator in many federally funded projects. On a policy level, Internet2 monitors, analyzes and advocates on federal Internet policy issues. The federal government has its own advanced Internet initiative, the Large Scale Networking Effort, and more recently, the National Science Foundation has created the Office of Cyberinfrastructure to stimulate advances in science and engineering research and education. To sustain and achieve both national and international goals for the advancement of Internet technologies, the United States government, along with international network organizations, are critical partners for Internet2.

National LambdaRail

At a national level within the United States, one new partnership is currently under negotiation between Internet2 and the National LambdaRail (NLR). In the summer of 2005, the Internet2 Board and the NLR Board voted to pursue discussions of a merger of the two consortiums. A consortium of leading U.S. research institutions and private sector technology companies, the NLR owns and operates a national fiber-optic network that covers 10,000 miles across the United States. According to Tracy Futhey

(2005), chair of the NLR board of directors, “as long as the two organizations have a shared goal and can provide complementary benefits, they can find ways to harmoniously coexist, be that in the current organizational forms and with the existing services of each or in some modified organizational structure” (p. 81).

International Partners

Internationally, Internet2 has partnered with over 40 organizations in Latin America, South America, Canada, Asia, the Pacific Rim, Europe, and the Middle East. The link between Internet2 and their international counterparts is a memorandum of understanding (MoU), which allows the international advanced network organizations to participate in Internet2 activities and connect to Abilene via a NGIX (next generation Internet eXchange point), gigaPop, or a peer network (Internet2 2005g, 2005l). The goals of the international partnerships are critical for Internet2 to ensure global interoperability, to enable research and education on a global scale, and to enable global collaboration between faculty, researchers and students with their international colleagues (Internet2 2005k). Internet2 international partners are organizations that have similar and parallel goals to Internet2, however they are not Internet2 members and do not pay membership dues.

Membership in the Internet2 Consortium

Membership in the Internet2 consortium is open to U.S. universities, corporations, and nonprofit research-oriented organizations (Internet2 2005p). To become a member of Internet2 there is a very specific and structured application process for each of the four different types of membership options: university (or regular), corporate, affiliate, and association. Corporations have three options for membership, which include corporate partner, corporate sponsor, and corporate member. Setting these three options apart are the expectations of goods and services that corporations will contribute to university or affiliate members. Those applying for affiliate membership can apply as an affiliate member or affiliate members with collaboration site status (Internet2 2005m).

Members of Internet2 do not automatically become connected to the high-speed backbone of the Internet2, Abilene. Only university members, affiliate members with collaboration site status, or a corporate collaboration site can connect to Internet2 high-performance networks. As of January 1, 2007, the membership types eligible to become connected to Abilene pay annual dues of \$30,000. In addition, they pay a \$22,000 Abilene primary participation fee as well as Abilene connection fees. The Abilene connection fees are bandwidth dependent and can cost anywhere from \$220,000 for OC12 SONET to \$480,000 to 10 GgE (10 Gbps). Those membership types not eligible for Abilene connections pay according to their membership type with annual costs ranging from \$2,700 to \$12,000.

THE INFRASTRUCTURE

Presently, the underlying foundation of the Internet2 infrastructure is based on a series of simple to complex connections to a high-performance backbone network

known as Abilene. Internet2 members may be connected to the backbone through universities, affiliate members, regional networks or gigaPOPs, which serve as network hubs or aggregation points. Abilene provides advanced network capabilities to Internet2 members in all fifty states as well as Puerto Rico and the District of Columbia. Internet2 connections are also available to Abilene sponsored participants such as community colleges, hospitals, museums, and colleges and universities as well as to Abilene Sponsored Education Group Participants (SEGPs).

Networks

In operation since 1999, the Abilene network was named after a railhead established in Kansas in 1880. Like its namesake, Abilene sees itself on the edge of a new frontier and has set its sights on providing an advanced network that will support innovative applications, advanced services not available on the commodity Internet, global connectivity to advance collaborative research efforts, and access to a rich source of data collections (Abilene 2006c). Currently, the Abilene network “is an OC-192c (10 Gbps) backbone employing optical transport technology and advanced high-performance routers” (Abilene 2006b, 1). Capable of providing speeds of 10 gigabits per second, the goal of the Internet2 Abilene dual-stack IPv4/IPv6 network is to “offer 100 megabits per second of connectivity between every Abilene connected desktop” (Abilene 2006a, 1). The transmission speed of Abilene, 10 Gbps, is more than 15,000 times faster than a typical home broadband connection (Pollak 2004).

The main concern with the standard Internet Protocol, IPv4, is that it has been deemed inadequate to handle the volume of addresses needed to connect wired and wireless computers, handheld devices, cell phones, and other mobile electronic devices to the Internet. On the other hand, IPv6, the upgraded Internet Protocol, promises to deliver an estimated 340 trillion trillion addresses; a vast improvement over the 4 billion addresses currently available (Internet2 2006d). This enhanced Internet Protocol will offer improved security, efficiency, and quality of service.

As IPv6 is deployed around the globe, more applications will be designed to use it, including high-quality streaming and interactive video that has become integral to the work of the research and education community. Internet2 members will be able to take advantage of IPv6 multi-cast connectivity not only within the Abilene network but also with their peers in Asia and Europe, where IPv6 deployment is progressing very quickly. (Rotman, L., personal communication, October 31, 2005)

One way to test the speeds and capabilities of new advanced networks is via the Internet2 Land Speed Record competition. The Internet2 Land Speed Record competition was inaugurated in 2000 by computer science pioneers Jim Gray and Gordon Bell who understood that “to realize Internet’s full potential, end-to-end network performance needs to take a huge leap forward” (Internet2

2006b, 1). The first Land Speed Record for the highest bandwidth, end-to-end networks using IPv4 was set in March 2000 with a transmission rate of 751 megabits per second. In 2005, the Land Speed Record using IPv6 was set with an average throughput of 5.58 gigabits per second. This competition had led to some break through speeds culminating in April 2006 when an international team lead by the University of Tokyo transferred data using IPv6 at a rate of 6.96 Gbps and IPv4 at a rate of 8.80 Gbps. Although it is believed that the latest IPv4 record may be the last using 10Gbps networks, new networking techniques may mean increased performance for future IPv6 networks.

Current research is now pushing the standard infrastructure for network architecture. Both the standard internet protocol, IPv4, and the upgraded internet protocol, IPv6, use IP packet switches as the basis of their infrastructure. This is currently changing as new research in networking is currently being conducted. The Internet2 Hybrid Optical and Packet Infrastructure (HOPI) project is currently developing and testing an infrastructure that consists of a hybrid of packet and circuit switched optical networks. Tests and experiments on hybrid networks are currently using resources from both the Internet2 Abilene network and the National LambdaRail infrastructure. In early 2006 it is being reported that the experiments done so far have been “used to create dedicated transcontinental network circuits that reliably transmit terabytes of radioastronomy data” (HOPI 2006, 2). Critical to the reliable transmission of such vast quantities of data is the software, or middleware, that creates the link between the network and the application. Researchers are inventing new middleware that will facilitate the unprecedented sharing of intellectual resources.

Middleware

Middleware is Internet2’s system of standardizing identification, authentication, authorization, directory, and security services to allow for a smooth and secure collaboration between members. To meet the mission of systemizing core services at Internet2 universities (Internet2 2006c), a number of core activities address the fundamental infrastructure in order to promote policies and best practices:

- Authentication of core identity
- Permissions for authenticated users
- Interoperability of databases
- Clarify identifier types, forms, and policies
- Address issues related to the use of certificates for individual authentication, email encryption, digital signatures, and access control

Additionally there are middleware development projects addressing unique issues related to healthcare education and practice, mailing-list services, and video conferencing. Essential to the operation and development of the Internet2 networks and middleware initiatives are the associated research and development initiatives focused on network security.

Security

Current approaches to network security on today's commercial Internet cannot meet the security requirements of high-performance and advanced networks. A few different affiliated, yet independent, organizations, and task forces have formed to collaborate on the challenges that exist relating to network security and Internet2. Internet2 security initiatives are advised by SALSA, a group of leading campus network security architects (Internet2 2005n) and is considered to be "future-oriented and state-of-the-art in nature, focusing on high performance and advanced networks" (Internet2 2005r; 1). Their task is to address the issues related to security architecture and how it interrelates with network performance, deployability, support, and protection. Working groups within SALSA have formed to look deeper at specific issues related to authorized network access, transit traffic, forensic support for investigation of abuse and the deployment of a pilot federated wireless network authentication system (EDUCAUSE 2005).

Internet2 security initiatives are also part of the Computer and Network Security Task Force. Various working groups within the Computer and Network Security Task Force work to pursue projects and initiatives related to four strategic goals: 1) education and awareness, 2) standards, policies, and procedures, 3) security architecture and tools, and 4) organization and information sharing. Such working groups and task forces are an integral part of the Internet2 community and serve to "provide intellectual capital and shared will to develop solutions" (Internet2 2006g, 1).

Development Activities

In early 2006, there were nineteen active working groups (WGs), sixteen special interest groups (SIGs), and ten advisory groups (AGs). WGs perform specific tasks, SIGs are mainly issue driven discussion groups, and AGs bring in a specific expertise to work with one or more working groups. Most of the groups have Web sites that specify their goals, purpose, members, and progress.

APPLICATIONS OF INTERNET2® TECHNOLOGIES

The applications being developed for Internet2 are so advanced that they are expected to significantly change and improve how we conduct research and engage in teaching and learning in higher education (Internet2 2005h). Attributes unique to Internet2 applications include such features as interactive collaboration, real-time access to remote resources, large scale, multisite computation and data mining, shared virtual reality, or any combination of these attributes (Internet2 2004). Once developed, these applications will not run on today's commercial Internet, because they require advanced networking features such as high bandwidth, low latency, and multicast (Internet2 2005h). The National Laboratory for Applied Network Research, via their Advanced Applications Database (AAD), and Pace University, via their Base² System, are two

examples that provide Web-based searchable databases of advanced software applications developed and running on advanced networks such as Internet2 (Base2 2005; NLNR/DAST 2005).

Members of the Internet2 community who wish to keep abreast of Internet2 application priorities and initiatives can look to the Applications Strategy Council (ASC), Industry Strategy Council (ISC), and the Network Research Liaison Council (NRLC) for current information. Although each of these councils have specific goals, their missions are interrelated. The ASC advises on matters related to the design and development of applications for research and education (Internet2 2005b). The ISC provides a strategic vision related to advanced networking and applications development and helps focus technology transfer aspects of Internet2 initiatives (Internet2 2005e). The NRLC helps identify priorities related to adapting computer systems to fit the Internet2 infrastructure, including research, access, and prototype deployment (Internet2 2005q).

The development of Internet2 applications spans across a number of disciplines from science and engineering to the arts and humanities. The following sections provide insight into some of the Internet2 applications being developed in four broad disciplines.

Health Sciences

Current Internet2 health science applications include areas such as medical education, virtual reality, and telepathology all of which require advanced network capability (Internet2 2005j). The Department of Community Medicine at West Virginia University School of Medicine uses Internet2 technology to conduct their monthly Public Health Grand Rounds series allowing practitioners from around the world to participate in discussions of case histories related to public health concerns (*Public Health Grand Rounds WebCast* 2005). To promote use and understanding of advanced networks and their applications in healthcare, the National Library of Medicine is working with Internet2 to showcase their tutorial "Advanced Networks and Applications in Healthcare." Such tutorials are being developed as a way to inform health care providers about the advantages of high-performance networks in delivering healthcare (Internet2 2005o).

At the same time, doctors at Stanford University have created a Virtual Reality experience for medical students called Anatomy and Surgery Simulation Over the Internet project. The purpose of this project is to teach surgical techniques online. By having access to an anatomical database over Internet2, students can manipulate anatomical structures by seeing it in multiple dimensions as well as feel the anatomical structure with a new technology called haptics (Ackerman 2003).

Arts and Humanities

Innovative Internet2 applications in the arts and humanities include collaborative live performances, master classes, and remote auditions (Internet2 2005i). There are currently many different types of pilot music projects being conducted to test the capabilities and limitations

of the advanced networks available today. Many of the Internet2 applications in the arts and humanities are using a medium called the Access Grid. The Access Grid allows users to interact simultaneously via multi-conferencing from up to fifty different sites around the world (Deal 2005) allowing for the broadcasting of productions from remote locations. For example, the *Cultivating Communities: Dance in the Digital Age* project conducted at the fall 2002 Internet2 member meeting featured a showcase of regional dance and music from the University of Southern California where live performers interacted remotely with performers from the University of Oklahoma, University of Illinois at Urbana—Champaign, New World Symphony in Miami, FL, Case Western University, and the Cleveland Institute of Music.

Additional exciting and relevant applications of this technology are also being used by museums and archeologists, as well as by foreign languages instructors (Doyle 2005). For example, the University of Pennsylvania Museum of Archeology and Anthropology recently used Internet2 to collaborate and consult with master Tlingit, fiber craftsman from Alaska, to examine 100-year-old textiles and baskets over a 3,000 mile distance. They employed Internet2 and DVDs to examine and discuss the pieces (Internet2 2005c).

Science and Engineering

Current Internet2 applications in science and engineering are centered on collaborative initiatives for data mining and data storage, multisite computation, real-time access to remote resources, and shared virtual reality (Internet2 2006f). For example, scientists from MIT have demonstrated how Internet2 can be applied to the field of radio astronomy in the electronic transmission of very long baseline interferometry (e-VLBI) data. As data was being transmitted from the Haystack Observatory in Massachusetts and NASA's Goddard Astronomical and Geophysical Observatory in Maryland, the data correlation was simultaneously being displayed in a 3D plot at a remote site in Pittsburgh. This sharing of highly sophisticated instrumentation facilitates the collaboration of a scientific community separated by geography.

Another exciting application made possible by Internet2 is tele-immersion. Electronic Visualization Laboratory (EVL 2006) at the University of Illinois Chicago has been partnering with engineers and scientists across the nation to develop tele-immersion, which they define as:

collaborative virtual reality over networks, an extension of the "human/computer interaction" paradigm to "human/computer/human collaboration," with the computer providing real-time data in shared, collaborative environments, to enable computational science and engineering researchers to interact with each other (the "tele-conferencing" paradigm) as well as their computational models, over distance.

This sophisticated technological process allows virtual excursions through the human body, machines, and

buildings; virtual visits to historical sites; as well as "environments that explore truths about irony, humor, music, and levels of consciousness" (Lemley 2002, 1) in which one can experience virtual physical experiences such as jumping off a set of stairs. Taking advantage of national and international high-speed networks, EVL's goal is to move from the laboratory to the next generation Internet where they can "access distributed computing, storage and display resources more efficiently than ever" (EVL 2006).

Education

Educators and students at all educational levels are creating innovative ways to communicate, collaborate and learn. Examples of education applications range from a live high-quality multicast stream of Washington University's May 2005 commencement activities to a virtual studio space developed to enable simultaneous teaching and learning space for a viola maestro and student separated by continents. Communication students at Northwestern University connected with political candidates and staff via videoconferencing over Internet2 high-performance networks; students from Bradley University and California State University, Los Angeles, learned from professionals in a screen writing course; Manhattan School of Music collaborated with Columbia University to present a live jazz combo performance over Internet2's Abilene Network; and the University of Delaware is collaborating with teachers and students at the Delaware School for the Deaf to bring in specialized student tutors from remote sites across the United States.

Internet2 access has also provided the K-12 community opportunities to take advantage of its high-speed networks and video conferencing capabilities. In its third year, the Megaconference Jr. took place in May 2006 and provided an opportunity for elementary and secondary students from around the world to participate in learning activities designed to build international cultural awareness (Megaconference 2006). Additional Internet2 and K-12 partnerships have spawned programs such as Read Across America; re-enactment of the Lewis and Clark expedition for K-12 schools; the Jason Project, an inquiry based science learning adventure; and the Internet2 Jazz Concert, a collaboration between university and K-12 music programs. The following case studies provide further examples of how Internet2 technologies are being used in K-20 educational settings and beyond.

CASE STUDIES

School Children, High-Speed Networks, and New Educational Opportunities

The National K-20 initiative was prompted by the decision of the Internet2 technology community to bring together those who would use the services and tools with those who are creating the advanced network applications. The Sponsored Education Group Participant (SEGP) process enables members to sponsor organizations outside of Internet2, which means that entire state educational networks have the opportunity connect to Abilene. Through the SEGP, education innovators in K-12, community colleges, universities, libraries, and museums have been

brought together to explore the ways that the advanced networking efforts developed by Internet2 can be used collaboratively to enhance teaching and learning (Internet2 2006a). Currently, there are 34 state education networks connected to Internet2.

Two Internet2 members sponsored by the Massachusetts K-20 Initiative, the University of Massachusetts Amherst and Worcester Polytechnic Institute, are connected to the Abilene backbone through the Northern Crossroads (NoX) gigaPoP. One part of this K-20 initiative is the Merrimack Education Center (MEC), which connects over 2/3 of the K-12 schools in Massachusetts, although not all at high speed.

There are a number of innovative educational projects designed to engage students in real-world applications. One such project was developed through the partnerships of MEC Technology System (MECnet) and the Jason Project to bring interactive science and math curriculum to students in grades 4 through 9. Named after the mythical Greek adventure, Jason and the Argonauts, the Jason Project was founded by Dr. Robert Ballard, one of three scientists who discovered the Titanic. MECnet (2004, 1) describes the Jason Project as one that “combines genuine scientific expeditions around the world, standards-based science and math classroom curriculum and professional learning for teachers to deliver real adventures in learning and measurable gains in student achievement.” This inquiry-based learning project is enhanced by online digital laboratories, probeware, online communications, and online assessments made possible by Internet2 technologies.

The Jason Project has also partnered with experts such as NASA to explore “Earth and Mars,” ecologists and geologists to explore the “Disappearing Wetland,” and anthropologists and entomologists to explore “Rainforests at the Crossroads.” High bandwidth streams and videoconference events with scientists are made possible to schools with limited resources through the relationship with Internet2 organizations in the K-20 community.

Orchestras, Auditions, and Master Classes

On March 18 2004, the first ever National Internet2 Day, a jazz combo from the Manhattan School of Music used the Internet2 connection at Columbia University to broadcast a live music performance to a live audience in Ann Arbor, Michigan. Simultaneously, the performance was multicast to over thirty Internet2 members nationwide who were participating in National Internet2 Day. This is one example that demonstrates how the arts and humanities have been one of the greatest benefactors of Internet2 technologies. Although Internet2 will not and is not intended to replace or eliminate live, in-person music education, it provides opportunities for augmentation of traditional methods to music performance education (Shephard 2005).

Internet2 technologies are becoming so advanced that they are able to handle the elements critical in music performance education such as sound, rhythm, timing, visual imagery, and movement. Such technologies are able to support the requirements for high-quality

audio and video over the Internet including low-latency, high-bandwidth transmissions of high-fidelity, stereo or multi-channel sound with accompanying full-motion video using broadcast quality standards (Orto 2004).

In the music world, master classes are music classes taught by, or consultations offered by, nationally or internationally acclaimed musicians. Mirabai Weishmehl, a student at New World Symphony, participated in a master class with Gordon Nikolitch, who is the London Symphony Concert Master. Both musicians were in geographically separate locations for the master class, however, as a result of Internet2 technologies they were able to experience high quality and clarity of sound with the immediacy of video presentation expected by a master musicians.

Conducting music performance education, including live performances, auditions, and master classes, over Internet2 is not without its challenges. Musicians who participate in such videoconferencing events rely on trained technologists to minimize echo in the transmission, to create high-quality full motion video and real time interactivity. In early 2005, Internet2 in collaboration with the New World Symphony offered a hands-on performance and master class production workshop. Such workshops have been established to train technology staff how to set up the equipment, maintain communication systems, and design the stages for interactive media events.

ENCOURAGING INNOVATIONS OF INTERNET2®

Exciting developments are constantly being innovated and deployed by Internet2 members. Such developments are enabling new collaborations, capabilities and experiments never before possible. Encouraging innovations of Internet2 are being seen across all spectrums of disciplines within higher education.

The NASA Research and Education Network (NREN) project will continue to use its Internet2 high-performance networking technologies to conduct advanced research and support collaborative applications. “A major goal of the NREN Project is to enable the fusion of emerging network technologies into NASA mission applications, resulting in new paradigms for conducting science across all NASA Enterprise Programs” (NREN 2006, 1). The NREN project has a number of ongoing applications such as the Virtual Collaborative Clinic (VCC), which involves key concepts such as telemedicine, virtual reality, and 3-D imaging with the long-term goal of introducing VCC to astronauts on the Space Station.

The Library of Congress plans to use its Internet2 membership “to collect and preserve the digital heritage of the nation” (Internet2 2006e, 1). The Library’s National Digital Newspaper program plans to create a digital resource of newspapers from the United States and its territories published between 1836 and 1922.

The Motion Picture Association of America (MPAA) and the Recording Industry Association of America (RIAA) are among the newest corporate members of Internet2 who hope to take advantage of the research and academic collaborative in order to develop a secure environment for the distribution of their media. This is an important time for

RIAA to become an Internet2 member, especially after the legal issues that ensued in 2005 with i2hub, a file-sharing service that allowed college students to use Internet2 to share copyrighted materials.

Although still in its infancy, the National Health Information Network (NHIN) is working toward a common framework for standards, policies, and methods for creating a health information exchange. The goal for such an exchange is to improve patient care by allowing appropriate individuals to request and retrieve patient health records rapidly and accurately. Such innovations are endorsed by the Internet2 consortium.

Internet2 CEO, Douglas Van Houweling, warns that “it is only a matter of time before consumers will make the same capacity demands on the network in their day-to-day use of network applications that the research and education community has today” (Talbot 2005, 1).

THE “NEUNET”

In his address to the Internet2 Spring Member Meeting, Douglas Van Houweling (2006) talked about the challenges that lie ahead for Internet2. Chief among his concerns was the merger of Internet2 and National LambdaRail (NLR). Although negotiations about the merger had broken down in April 2006, he expressed the Internet2 commitment of moving the Abilene network to the NLR infrastructure. Such a merger will allow for a focus on use and innovation, rather than on maintenance. Larry Faulkner, Chairman of the Board of Trustees of Internet2 confers that to best meet the needs of higher education in the United States there needs to be “a single strong agile structure” and a “unified organization” that can handle the challenges that lie ahead (Faulkner 2006).

To emphasize the importance of working together, the Internet2 CEO introduced the term “newnet.” Van Houweling stressed the importance of collaboration and looking to the future while building upon the heritage of the work and research that has already been accomplished. As a way to respond to the complex challenges inherent in building such advanced technologies, the governance structure of the Internet2 consortium is changing and attempting to create closer ties between national and regional infrastructures and federal agencies which will be a necessity if they are to serve the Internet2 member universities. Van Houweling acknowledged the importance of international partners and emphasized the continued need for global collaboration and integration, noting that the “best ideas are coming from all over our world” (Van Houweling 2006). Finally Van Houweling reiterated that the focus of Internet2 is to provide a network to the “people who have new visions for applications that can be enabled using this network,” whereas at the same time reminds us that “we need to imagine a future that is yet to be invented.”

GLOSSARY

Abilene: An advanced backbone network that connects regional aggregation points (gigaPoPs) and supports the work of Internet2 universities.

Gigabit point of presence (gigaPoP): A regional Internet working aggregation point used for accessing the Internet2 network.

Hybrid optical and packet infrastructure (HOPI): An Internet2 initiative that is designing and building a network that is a hybrid of packet- and circuit-switched optical network infrastructures.

Internet protocol version 6 (IPv6): Called the next version of the Internet protocol replacing Internet Protocol version 4, which is used by the current Internet.

Middleware: The layer of software between the application and Internet2 network which provides services such as identification, authentication, and security.

National LambdaRail (NLR): is a consortium of leading U.S. research universities and private sector technology companies that has deployed 10,000 miles of fiber optic cable across the United States.

Next generation Internet eXchange point (NGIX): A facility where federal research networks connect with each other and with other advanced networks.

University Corporation for Advanced Internet Development (UCAID): The nonprofit organization manages the activities, programs, dues, and expenditures of Internet2.

Sponsored Educational Group Participants (SEGP): A type of indirect Internet2 membership which enables members to sponsor organizations outside of Internet2.

INTRODUCTION

Any person who has used the Internet is familiar with the names of popular Web sites such as online bookstores (www.amazon.com), government departments and agencies (www.parliament.uk), business corporations (sony.co.jp), and news organizations (www.cnn.com). These easily remembered Web addresses, called domain names, are part of a two-part name-and-number addressing system that uniquely identifies every device connected to the Internet. The other part is 32-bit Internet protocol (IP) addresses, associated with each domain name. Together, this two-part naming system called the domain name system (DNS), makes all Internet communication possible.

A two-part addressing system is necessary in part to enable human users to interact with a computer network. If all Internet communications were between machines, unique IP addresses alone would have sufficed—for example, a network enabled printer connected to an office computer requires only an IP address. However, it would be impossible for human users to interact with a system based only on numerical addresses due to the obvious limitations of human memory recall. Though the advent of better search engine technologies have reduced the importance of domain names as mnemonic devices, users may still find it easier to remember the domain names of their most-visited Web sites, rather than strings of abstract numbers. A two-part naming system has other advantages as well: since external users only use the domain name, and never interact with the IP addresses, an organization can easily route traffic to multiple servers at high-traffic Web sites by mapping multiple IP addresses to the same domain name. Server shut down and maintenance is also facilitated by this system, because traffic can be rerouted internally without affecting the public presence of the organization. Thus, for multiple reasons, the DNS has become one of the key technical infrastructures of the Internet. This article discusses its technical, institutional, and policy aspects, in that order.

TECHNICAL DESCRIPTION

In the early days of the Internet, when the network connected only a few computers at government research labs and universities, the addressing system was contained in a simple text file called `hosts.txt`, that identified each host computer connected to the network by a simple name, and provided basic information about it including location and network address. Whenever new computers were added to the network, the `hosts.txt` file would be updated and a new version mailed out to all host computers. This simple system sufficed to take care of addressing needs for the first decade or so of the Internet's early history.

However, as the number of hosts on the Internet gradually grew, this early addressing system proved inadequate (National Research Council 2005). The system failed to scale because the `hosts.txt` file became enormously large as the number of computers increased. The traffic demands too grew exponentially as an updated file had to be sent out to the thousands of networked computers whenever a new one was added, or the particulars of an existing one changed. New hosts were effectively invisible to the rest of the network until an updated `hosts.txt` file was mailed out and installed on each computer. Naming conflicts were also inevitable because of the logistical problem of finding unique names for every host on the burgeoning Internet. It thus became inevitable that a new naming system had to be devised.

The current domain name system was organized in response to this pressing need. It envisions a hierarchical and distributed naming system organized in an inverted tree structure, beginning with the “root” server at the very top (see Figure 1 below). At each level a “name server” contains the authoritative listing of all domain name assignments in the layer immediately below. Under the “root” are a number of top-level domains (TLDs), classified as generic top-level domains (gTLDs) (also commonly called global top-level domains) and country-code top-level domains (ccTLDs). Name servers in each TLD contain the

Figure 1: Inverted tree structure (partial) of the domain name system

list of all secondary level name assignments made within that top-level domain. The secondary level domains may in turn be sub-divided into further hierarchical layers. The paragraphs that follow provide additional information on the structural elements of the DNS.

The Root

In conformity to the inverted tree architecture of the domain name system, its highest level is called the root. The key root resource is the root server, that contains an exhaustive listing of all top-level domain assignments, that is, it identifies IP address for the authoritative name server (see below) for each top-level domain under the root. Since it is critical that access to the root server be available at all times, the DNS has duplicated the contents of the root on root servers located on different continents. Currently, there are thirteen root servers designated by the letters A to M (see Table 1). Each root server is maintained and operated by organizations called root server operators: these include private firms, universities, government research laboratories, and international consortia. While several of the root servers are located on single servers at one location, others (C, F, I, J, K, and M) are mirrored at dozens of sites around the world using a technology called *anycast*, that routes addressing queries to the nearest root server. This redundancy ensures that local outages, server failures, and so on would not deprive the Internet of one of its most essential resources.

Top-Level Domains

The name space under the root server is divided into a number of top-level domains. Generic TLDs (gTLDs) organize domain names into categories based on type of organization or subject interest. They include the popular '.com' space for commercial businesses, the '.gov' space for U.S. government Web sites and '.edu' for educational institutions (see Table 2 for a list of gTLDs as of end-2006). Some of the gTLDs are 'sponsored' and serve a narrow community of interest (for example, .aero), whereas others are unsponsored, with domain name assignments available to all users (for example, .com). Country-code TLDs (ccTLDs) are assigned to different countries, such as '.uk' for the United Kingdom. To avoid political controversy, ccTLD assignments are based strictly on the two-letter list of

nations and sub-national regions maintained by the International Organization for Standardization (ISO), which in turn is based on United Nations sources. Currently, there are approximately 250 ccTLD designations in the DNS databases. In addition to gTLDs and ccTLDs, the DNS also contains a special purpose 'infrastructure' TLD, .arpa, used by the system for technical coordination purposes.

Each top-level domain has an authoritative TLD name server. Name servers are special computers that exhaustively list all domain names and IP addresses belonging to a section or subsection of the Internet, for which that name server is considered to be authoritative (Mockapetris 1983a). In addition, name servers are equipped with address resolution software such as the popular Berkeley Internet Name Domain (BIND) program that can identify the IP addresses associated with domain names in other zones when queried by users.

Domain Names

The domain names of the DNS comprise of two or more parts or labels, separated by dots. They are character strings set up according to a few simple, yet rigorously enforced rules. Domain names may be 1 to 63 characters long, and can use a limited subset of ASCII, namely the 26 alphabets, the 10 numerical digits, and the hyphen.

It may be worth pointing out the distinction between uniform resource locators (URLs) and domain names. An example will clarify this: Penn State University's Web site is located at the domain name www.psu.edu, accessible at the Web address, <http://www.psu.edu>. The arrangement of both the domain name and the Web address indicate the hierarchical levels to which they belong in reverse order, that is, right to left. The assignments are made within the .edu gTLD intended for educational establishments, within which the second-level domain name [psu.edu](http://www.psu.edu) is assigned by the DNS to Penn State University. The third-level assignment www.psu.edu is made internally by the host organization.

As mentioned before, not all Internet devices require domain names to be assigned. Domain names are required only where human users need to interact with the technical system.

IP Addresses

In addition to domain names, IP addresses are the second part of the name-and-number DNS system (this section is based on Hall 2000; see especially Appendix B, IP Addressing Fundamentals). IP addresses are number strings of fixed bit length: 32 bits in the common IP version 4 (IPv4) assignments, or 128 bits in IP version 6 (IPv6). IP addresses in IPv4 are commonly represented as four numbers between 0 and 255, separated by dots. For example, the Web site for the U.S. Congress, www.congress.gov, maps to 140.147.248.209. IPv6 addresses are represented in the hexadecimal (base 16) system, as eight number-letter strings separated by colons.

In IPv4, there are two sub-addresses as part of the IP address, the network prefix, and the host ID. The network prefix is assigned by a central authority to network

Table 1: Root Servers and Their Locations

Server	Operator	Locations	IP Address
A	VeriSign Naming and Directory Services	Dulles VA	198.41.0.4

providers, who then assign the host IDs to machines on their networks. The length of the network prefix is identified by a separate 32-bit identifier called the subnet mask: the remaining part of the IP address then becomes the host ID.

When users type in domain names into their computer's browsers, the computer is able to "resolve" or identify the associated IP address. Domain names and IP

addresses need not be mapped one to one. In some cases, for example when a manufacturer wants to promote multiple brand names, several domain names may point to the same IP address for the content server on which all of the company's Web-accessible information is stored. In other cases, a network administrator may want to have the same domain name associated with multiple content servers, to ensure access during periods of heavy usage.

Table 2: List of Generic Top-Level Domains (gTLDs) as of 2006

gTLD	Introduced	Available to:
.aero	2001	air transportation industry
.biz	2001	business; open to any registrant
.cat	2005	Web sites in the Catalan language
.com	1995	commercial; open to any registrant
.coop	2001	cooperative organizations
.edu	1995	educational institutions, mainly in the United States
.gov	1995	agencies and departments of the U.S. government
.info	2001	any type of information; open to any registrant
.int	2001	international agencies and organizations
.jobs	2005	human resource agencies
.mil	1995	U.S. military
.mobi	2005	mobile content providers and users
.museum	2001	museums
.name	2001	individuals
.net	1995	network providers; open to any registrant
.org	1995	organizations not included elsewhere; open to any registrant
.pro	2002	professionals such as lawyers, doctors etc
.tel	2006	Internet communications
.travel	2005	travel and tourism industry

Source: ICANN Registry Listing, available <http://www.icann.org/registries/listing.html>.

Traffic could be routed to whichever server that has spare capacity at that moment.

To facilitate communication between different networks, Internet routers have ‘routing tables’, which identify a pathway through the network from each network prefix to every other network prefix. Thus, the size of routing tables increases exponentially as the number of network IDs increases. Not all network prefixes have direct routes assigned in all routing tables, in which case they will be routed with extra “hops.” Network prefixes with direct listings in the highest level routing tables (on the backbone) are the most valuable, because they can be reached with the fewest “hops.”

Network prefixes were initially assigned in five ‘sizes’: classes A to E (Hall 2000; Mueller 2002). Class A networks use the first 8 bits for the network prefix, and the remaining part of the fixed-length IP address (32 bits) to identify the host ID. Since each network and host needed to be assigned a unique number, only a limited number of class A networks are available to be assigned; however, these networks could accommodate a large number of hosts. Class B networks used 16 bits for the network prefix, with the effect that there could be a larger number of class B networks, though they were smaller in size. The most common category is class C networks with less than 256 hosts. Class D networks are used for multicasting group addresses and E networks for experimental purposes.

This system of fixed size networks is called “classful” addressing.

One of the pressing problems confronting the Internet today is IP address scarcity, caused by the enormous growth in the number of networks connected to the Internet. When TCP/IP was being designed in the 1980s, it was projected that the numbering protocols would need to support 100,000 networks sometime in the remote future: that number was reached and exceeded by 1996 (Bradner and Mankin 1995). The original IPv4, with a 32-bit addressing space, is capable of generating approximately 4.3 billion unique addresses: this proved to be inadequate, especially when new devices such as wireless phones and even home appliances need to be connected to the Internet. Address scarcity was compounded by the fact that address blocks could be assigned only in fixed sizes, leading to wastage of IP numbers and additional entries in routing tables: for example, a network with an estimated size of 300 hosts would require two Class C networks to be assigned, with some IP addresses remaining unused, and two separate entries in routing tables. This resulted in exponential growth in the number of entries in routing tables, imposing additional processing costs on Internet routers.

From 1994, a number of steps were taken to solve these problems. One of the most commonly used solutions is dynamic IP addressing. Instead of assigning a permanent

“static” IP address to a node on its network, an Internet service provider may temporarily allocate an IP address from a common pool to a device using a protocol such as dynamic host configuration protocol (DHCP). These “dynamic” IP addresses are made available only for the duration of a session, and can be reassigned to other uses as they come online. Network address translation (NAT) was another technique that was promoted as a short-term solution to number scarcity, by enabling multiple nodes on a private network to share the same IP address (Egevang and Francis 1994). Each node on the private network is assigned a unique “inside local address” that the local NAT-enabled router recognizes, but is not transparent to the outside network. The router encodes outgoing messages with the common IP address, receives incoming data and redirects it to the appropriate machine. With NAT, a large number of private network nodes are able to share a limited number of “outside” IP addresses.

Another solution is classless inter-domain routing (CIDR) that allows flexible network prefix sizes, instead of the five standard classes that existed earlier (Fuller, Li, Yu, and Varadhan 1993). The length of the network prefix is easily modified by setting the subnet mask to the appropriate length. This enabled better utilization of the existing IP number space by increasing the number of network assignments that could be made, and tailoring the network sizes more closely to actual demand so that wastage could be limited. In effect, CIDR allows an Internet registry to divide up and allocate an address block in several different sizes to different organizations based on need. CIDR was also able to support hierarchical route aggregation, in which many traditional classful networks could be represented by a single entry in the routing tables. This checked for the time being the phenomenal growth in the number of entries in routing tables. Assignment policies were also tightened (Mueller 2002).

In spite of these measures, it was recognized that address exhaustion in the IPv4 space was eventually going to result. In response, the Internet Engineering Task Force (IETF) introduced a new numbering protocol called next generation Internet protocol or IPng (also called IP version 6, or IPv6), with a document titled *The Recommendation for the IP Next Generation Protocol* (RFC 1752) (Bradner and Mankin 1995). Detailed specifications were published in *Internet Protocol, Version 6 (IPv6) Specification* (RFC 2460) (Deering and Hinden 1998). The most important change in IPv6 was the expansion of the IP address size from 32 bits to 128 bits, increasing the total number of addresses that can be assigned to approximately 3.8×10^{E38} . The IP addresses in IPv6 are expressed in the format X:X:X:X:X:X:X:X, where each X is a four-digit hexadecimal (base 16) integer (3Com 2001). Since each digit in a hexadecimal system needs four bits for representation, each integer X requires 16 bits (4×4) and the whole IP address of 8 integers 128 bits ($4 \times 4 \times 8$).

In addition to expanding the number space, IPv6 introduced a number of innovations relating to routing, addressing and security. First, it added more levels to the addressing hierarchy: Internet registries and large Internet service providers are top level aggregators (TLAs) with very large address blocks assigned to them; in turn, specific customer sites are next level aggregators (NLAs)

to which smaller address chunks are assigned, and sub-networks within organizations are site level aggregators (SLAs) (3Com 2001). Each of these hierarchical levels is identified by a specific field within the IPv6 host address, so that traffic directed at user interfaces can be appropriately routed. This is similar to the route aggregation under CIDR. The advantage of this arrangement is that the number of entries in the global routing tables is kept to a minimum, with routers at each level directing traffic to the appropriate sub-hierarchical units. Smaller users would no longer be able to obtain address assignments directly from the registries under IPv6.

In terms of addressing, a significant innovation in IPv6 is the augmentation of addressing methods. As in IPv4, unicast addressing identifies a unique host interface as the recipient of a data transmission. In addition to this, IPv6 permits multicasting and anycasting as well (3Com 2001). Multicasting, where data is sent from one originating node to a group of packet recipients, is part of the basic protocol in IPv6 compared to IPv4 where it was optional. Anycasting enables a packet sent to an anycast address to be routed to the nearest or best of a group of interfaces, based upon network topology.

Another key improvement in IPv6 is enhanced support for privacy, and data security. The protocol includes extensions to support authentication and data integrity, as well as confidentiality through encryption. IPv6 allows the labeling of packets so that particular traffic flows such as “real time” services can be given special handling on the basis of sender requests. Finally, IPv6 allows server-less autoconfiguration, that enables any device to connect to the network without requiring the network administrator to assign an IP address using protocols such as dynamic host configuration (DHCP). The vastly expanded pool of available IP addresses in IPv6 allows all devices to be provided with “static” IP addresses, making the process of connecting to the network much simpler than before.

Address Resolution

One of the most important tasks performed by the DNS is address resolution, namely the matching of an IP address to the domain name typed into a browser or an e-mail program by a user. Originally, this was accomplished by looking up the corresponding IP address entry for the domain name in the hosts.txt file available on each computer. However, after the advent of the hierarchical and distributed DNS, there no longer exists a central repository of all domain name–IP address combinations. Address resolution therefore follows a multi-stage recursive process in which name servers at each hierarchical level of the DNS are successively queried, beginning with the root server. The discussion below is based on Mockapetris (1983b) and National Research Council (2005). Figure 1 illustrates the process diagrammatically.

The address resolution process begins when a user’s application program initiates a domain name query to a software program called a resolver resident on the user’s computer (Step 1 in Figure 2 below). Some resolvers are simple programs that only forward the query to a local name server belonging to the user’s Internet service provider, and then wait for the system to respond—these types

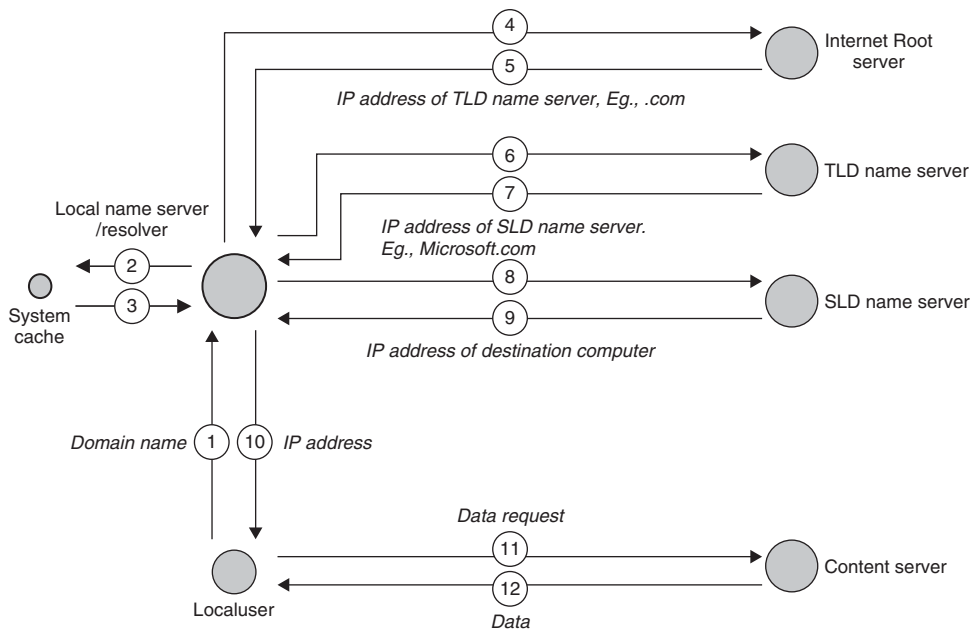

Figure 2: Steps in the address resolution process

of programs are called stub resolvers. More complex versions called iterative resolvers are capable of managing every stage of the resolution process themselves. Initially, the local name server checks its own resources to see if the IP address is available. For example, if the destination computer belongs to the same local network as the user, the local name server itself is authoritative for that space and will contain the needed IP address. In other cases, a local name server may maintain a cache, or memory of recent searches performed by local users. The cache is a feature put in place to reduce the enormous number of address resolution requests that are submitted to the DNS. If the search is available in the cache, the appropriate answer is delivered to the user's application program, and the resolution process is concluded (Steps 2-3 and 10). To maintain the cache at a manageable level, prior searches are retained in memory only for a specified period of time called the time to live (TTL).

If the destination computer is not local and a record of prior searches is unavailable in the cache, the next step for the local name server is to submit the request to the DNS. To do so, the local name server begins at the top of the DNS with the root server, and works its way down the hierarchy (Step 4). As mentioned above, there are 13 root servers distributed throughout the world, with several of these also mirrored at dozens of additional locations. The IP addresses for these root servers, called the root hints data, are manually entered into every computer and are constantly available. The local name server chooses one of these locations using a selection algorithm intended to minimize the response time, and submits the query. The root server examines the request and returns the IP address of the appropriate server at the next lower level, namely the top-level domains (Step 5). The resolver then sends a second query to the TLD name server requesting the IP address of the SLD name server, working its way progressively down the hierarchy until the IP address of

the destination computer is located (Steps 6-7 and 8-9) and sent back to the user (Step 10). Finally, once the user's computer has the IP address for the destination computer, a data request is initiated (Step 11), in response to which the host's content server sends the requested data (Step 12).

Sometimes, the local name server's cache may be able to resolve the address partially, for example by identifying the local network to which the destination computer belongs. In this case, the resolution process bypasses the higher levels of the hierarchy, and directly communicates with name servers at the local network level; that is, the process moves directly from Step 1 to Step 8, in which the IP address of the content server is requested from the SLD name server. The remaining steps then proceed sequentially. These protocols have been put in place to minimize the query volumes on the DNS as much as possible.

INSTITUTIONAL STRUCTURE

The operations of the DNS described above require the performance of a number of different activities including the assignment of domain names and addresses, address resolution, technical standard-setting, the creation of new top-level domains, dispute resolution, coordination and communication, and so on. In keeping with the decentralized, public-private, international, and inter-networked nature of the Internet itself, the management of these DNS activities is also diffused between several different agencies based in the private, public, and quasi-public spheres, cooperating through a complex set of institutional arrangements and relationships.

Historical Background

The current institutional framework for the DNS evolved out of a long and complicated sequence of events

(see Froomkin 2000; Mueller 2002; Pare 2003 for a detailed chronicle of these events: unless otherwise stated, the discussion in this section is summarized from these sources). Initially, when the Internet was confined to a few government research laboratories and university departments, many of these management functions were performed by one individual, Jon Postel, functioning as the director of the Internet Assigned Numbers Authority (IANA). A researcher and professor at the Information Sciences Institute at the University of Southern California, Postel derived his authority from a contract with the U.S. Department of Defense, that had funded the early Internet infrastructures. As the director of IANA, Postel assigned domain names and IP addresses, created new top-level domains as demand arose, and edited the Request For Comment (RFC) document series that laid out the technical and policy principles underlying DNS management.

As the Internet grew, and with it the demands on domain name administration, this ad hoc system could no longer fulfill the demands placed on it. In its place, a number of institutions sprang up to handle various aspects of Internet management. In 1986, the Internet Engineering Task Force was created to develop standards and protocols that promote the interoperability of the Internet, with the aid of all-volunteer, specialized working groups. The Internet Research Task Force (IRTF) is active in the same field as the IETF, but with a longer-term focus. Both these organizations are overseen by the Internet Architecture Board or IAB (formerly known as the Internet Activities Board). In turn, the IAB reports to the Internet Society (ISOC), an umbrella organization formed in 1992 to coordinate between the various ad-hoc organizations active in the management of the Internet. It accepts membership from both individuals and organizations.

Over time, DNS management acquired significant participation from for-profit, private corporations as well. In 1992, a private company, Network Solutions was licensed by the National Science Foundation to accept domain name registrations for the Internet. In 1995, as the number of registrations exploded (especially in the .com TLD), Network Solutions was authorized to charge a fee for registering .com addresses. In the year 2000, Verisign Incorporated acquired Network Solutions along with its DNS related businesses. Verisign continues to operate the gTLD name servers for two of the most popular Internet domains, .com and .net.

By the mid-1990s, the Internet had become an enormously popular global medium. This explosive growth and the increasing commercial use of the Internet brought to the fore a number of issues such as allegations of trademark violations in domain name assignments, the formation of new top level domains, control over new country-code TLDs and the creation of alternative root server systems in competition with the DNS (see Froomkin 2002; Mueller 2002; Pare 2003). By 1996, it became clear that changes in the DNS governance structure were an unavoidable need and key stakeholders put forward competing proposals for reform. The Internet Society, through a new organization called the Internet Ad Hoc Committee (IAHC), initiated a set of reform proposals called the generic TLD-memorandum of understanding (gTLD-MoU). It drew significant international attention and participation,

with ITU Secretary General Pekka Tarjanne (1997) hailing it as a new type of international organization, based on “voluntary multilateralism.” Alarmed at the potential loss of DNS control to an international entity, the U.S. government put forward a competing proposal called the Green Paper in January 1998, around which a ‘dominant coalition’ was gradually assembled, including formerly warring sides—the technical community led by Jon Postel, the large corporations, trademark interests, and some foreign groups and governments (“Improvement of technical management of Internet names and addresses” 1998).

The outcome of this process was a White Paper in June 1998, calling for a new not-for-profit private corporation, headquartered in the United States to administer the name and numbers system (“Management of Internet names and addresses” 1998). To assuage international concerns, the White Paper specified that the new corporation would have an internationally representative board and a membership drawn from all major stakeholders such as “IP address registries, domain name registries and registrars, the technical community, ISPs, and users including commercial entities, non-commercial users and individuals” (Mueller 2002, p. 174). Accordingly, a non-profit public benefit corporation called the Internet Corporation Assigned Names and Numbers (ICANN) was formed, based in California. In a Memorandum of Understanding with the U.S. Department of Commerce (DOC), ICANN was ordered “to transition management of the domain name system (DNS) from the U.S. government to the global community” (online), as well as to ensure stability, promote competition, support private-sector leadership in DNS management and policy-making and make the decision-making process representative of the global Internet community (ICANN 2004). The DOC-ICANN MOU has been periodically amended: the most recent amendment in September 2006 reiterated the commitment to private sector leadership in managing the DNS, and to protecting the stability and security of the Internet (Modification to Joint Project Agreement 2006).

In the following paragraphs, we discuss the main institutions and agencies active in DNS management, beginning with ICANN.

ICANN Structure and Processes

ICANN came into existence pursuant to the White Paper’s commitment to non-governmentalism, citing the greater flexibility and speed of private sector decision-making (“Management of Internet names and addresses” 1998, 31749). Accordingly in ICANN’s structure, there was only a limited role for government: the main decision-making body of ICANN is the board of directors with fifteen members selected by a nominating committee comprised of various Internet stakeholders. Directors are appointed for three-year terms. The corporation’s chief responsibilities include establishing the policies for the allocation of IP number blocks; overseeing the root server system; creating new top-level domains as required; and promoting standards and technical parameters that would ensure universal connectivity to the Internet (Memorandum of Understanding [MOU] 1998). Responsibility for IP number blocks and the root server system were originally

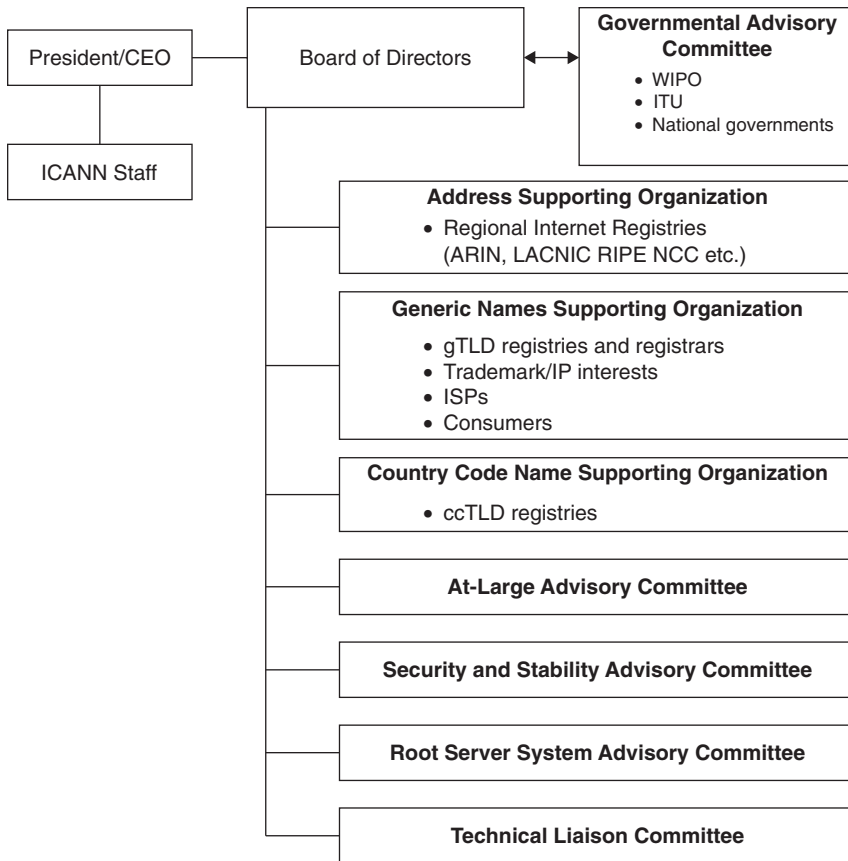

Figure 3: ICANN organizational chart

IANA responsibilities that were transferred to ICANN consequent to the MOU.

ICANN is aided by a number of supporting organizations and advisory committees, representing various Internet stakeholder groups (see Figure 3, adapted from organizational chart at ICANN, 2004 and Mueller 2002, p. 187). These include the Address Supporting Organization whose membership is drawn from the Regional Internet Registries, the Generic Names Supporting Organization (GNSO) representing various gTLD entities such as registries and registrars (see below), Internet service providers, users and intellectual property interests; the Country Code Name Supporting Organization, (CCNSO) representing the ccTLD managers; and the Technical Liaison Committee with membership drawn from the technical standards organizations, such as the European Telecommunications Standards Institute (ETSI), the International Telecommunications Union, the World Wide Web Consortium (W3C), and the Internet Architecture Board (IAB). In keeping with the private sector orientation of ICANN, national governments have no direct role in ICANN: they find a voice only on the Governmental Advisory Committee (GAC). The GAC would “consider and provide advice on the activities of ICANN as they relate to concerns of governments, particularly matters where there may be an interaction between ICANN’s policies and various laws and international agreements or where they may affect public policy issues” (Art. IX, Section 2(1)(a), ICANN Bylaws). The GAC has only a purely advisory

function, and no decision-making authority. This led some observers to herald ICANN as a new type of international organization, with a clear global mandate but no basis in multilateral treaty, and no role for national governments (Feld 2003; Mueller 2002).

Registries and Registrars

Until the formation of ICANN, Network Solutions, originally contracted by the U.S. Department of Defense in 1992 to accept domain name registrations, had exercised control over the operation of the root and important gTLDs such as .com, while continuing to offer retail registration services to customers. In a new agreement crafted with ICANN after the latter’s formation, Network Solutions agreed to separate its registry and registrar businesses. Registry operations involve the administration of the root server and the gTLD servers, whereas the registrar business entails assigning second-level domain names within the TLDs such as .com and .org. Only one registry is authorized for each TLD, whereas there are multiple registrars in each TLD name space.

Each TLD would have a monopoly registry entrusted with the responsibility of maintaining the authoritative list of domain name assignments within that name space. In addition, they are expected to fulfill several conditions as part of their registry agreements with ICANN (see for example the .com Registry Agreement, 2001, between Verisign and ICANN). Chief among these obligations

include providing registry services to the Internet community in a transparent and non-discriminatory fashion, upholding ICANN's dispute resolution policies in case of disputes about trademarks, and dealing only with ICANN-accredited registrars. In addition, registries are also required to financially support ICANN, through a complex system of a fixed registry level fee (a set amount each year, collected in equal installments quarterly), a registry level transaction fee (indexed to the annual increases in the number of new or renewal registrations, or inter-domain transfers in each TLD), and a variable registry level fee (with two sub-components, the first related to the total number of domain name registrations and the second to the number of registrars active in each TLD zone).

Within each TLD, many registrars offer retail second-level domain name registration services to customers. Registrars are required to fulfill a number of conditions relating to financial solvency, and would need accreditation from ICANN before Network Solutions and other registries will contract with them. Accredited registrars will pay a one-time fee to ICANN and an annual variable fee depending on the number of second-level domains they register. Registries are also authorized to collect an annual fee from each registrar offering domain name registrations in their zones, plus a fee for each name registration. Currently Verisign (a private corporation that acquired Network Solutions in the year 2000) serves as the registry for two of the most popular gTLDs, .com and .net, under a six-year renewable contract with ICANN and the U.S. Department of Commerce.

Regional Internet Registries

In addition to the procedures for administering domain names described in the previous paragraphs, a parallel system exists for IP addresses. It may be recalled that the allocation of IP addresses was one of the responsibilities of IANA, transferred to ICANN after the latter's creation. Currently, IP address allocations are handled by five Regional Internet registries (RIRs) formed in 1992: IANA allocates IP address blocks to the RIRs based on projections of need, as defined in the Global Addressing Policy (2005) document. The RIRs in turn assign IP number blocks to local Internet registries (LIRs) or Internet service providers.

Each of the five RIR has jurisdiction for a well-defined geographical region: the Asia-Pacific Network Information Center (APNIC) with jurisdiction over south, southeast, and east Asia and Australia; the African Network Information Center (AfriNIC) for Africa; the American Registry for Internet Numbers (ARIN) for North America excluding Mexico; the Latin American and Caribbean IP Address Regional Registry (LACNIC) for Central and South America and the Caribbean; and the Reseaux IP Europeens Network Coordination Center (RIPE NCC) for Europe, the former Soviet Union and central and west Asia (Internet Society 2005). The activities of these RIRs are coordinated through the Number Resources Organization (NRO), formed in 2003. The NRO liaises with the Address Support Organization of ICANN in matters related to the IP number management, such as framing the resource

allocation policies, creating new RIRs if needed, and other policy questions.

DNS POLICY QUESTIONS

As is evident from the previous discussion, the domain name system is not only a technical but also an institutional system, in which multiple political, economic, and social objectives need to be reconciled. It is also a system with distinct international ramifications, due to the global nature of the Internet and its rising importance for trans-border information flows and commerce. It is therefore not surprising that DNS policy has been heavily contested, with multiple agencies and interest groups vying for influence. In this section, we discuss some of the policy questions that have attracted considerable attention in the past, and continue to in the current environment.

Property Rights in the DNS

Ever since 1994, when Network Solutions began accepting a registration fee for domain name registrations, it has been popularly regarded that registrants have some form of ownership rights in the domain names assigned to them. The fact that domain names can be bought and sold, or otherwise transferred, has reinforced this notion. However, the question of what specific property rights are inherent in domain names has led to numerous disputes, including some high-profile court cases. One such case was *Kremen v. Cohen* where the domain name sex.com, originally assigned to the plaintiff, was illegally appropriated by the defendant on the basis of a forged letter and developed into a multimillion dollar pornography Web site (Soares 2001). When the plaintiff sued to recover the domain name, the key question for the court was whether a domain name was tangible property or intangible property. The tort of conversion, in which one party wrongfully interferes with the right of possession of the other, has historically applied only to tangible property. Though the court ruled to return the registration to Kremen, it refused to identify domain names as tangible property subject to conversion, leaving it to the legislature to define the appropriate standards. In contrast, the Virginia Supreme Court ruled in another case, *Network Solutions, Inc. v. Umbro International*, that domain names were not property at all, but only a claim to a service provided by the domain name registrar. Therefore, a domain name was not subject to garnishment, because services provided by a third party could not be used to satisfy monetary claims against a defendant.

Property rights claims in other parts of the domain name system have also proved to be controversial. In *Verisign v. ICANN*, Verisign claimed that ICANN's attempt to prevent it from offering a service called Sitefinder was an unlawful restriction on its ability to do business (McGwire 2004; Jayakar 2004). Sitefinder was a service that would redirect an Internet user who mistypes a Web address to a site managed by itself, listing alternative Web sites for the user to choose. Verisign was able to offer this service due to its status as the registry for the .com and .net gTLDs, and therefore in charge of the authoritative TLD name servers. Implicit in this suit was Verisign's claim that the database

of name registrations is also a registry's intellectual property, in which it has certain ownership rights. Network Solutions, Verisign's predecessor as the .com registry, had claimed in successive annual reports that the company had certain ownership rights in the database of information relating to customers in its registration business (Network Solutions 1998). The court dismissed the case citing insufficient evidence, but left the more fundamental question of property rights in registry lists unanswered.

All of these cases indicate the profound ambiguity surrounding the concept of property rights, as they are applied to domain names and registry lists. This question is likely to grow in importance with the increasing commercial value of domain names and other elements of the DNS. Some of these issues may need to be clarified by legislatures, and increasingly through international agreements. A question closely related to that of property rights is trademark policy.

Trademark Policy

Since the mid-1990s, a number of controversies have arisen over allegations by corporations that third-party registrants have registered trademarks belonging to them. Mueller (2002) has classified trademark conflicts into several categories: character string conflicts (registration by a third party exactly matches a trademarked name); name speculation (deliberate registration of names to resell it at profit to trademark owner); typo-squatting (registering names close to that of a popular site, to benefit from mistyped addresses—e.g., yahooo); parody (registering a competitor's or opponent's name to suppress communication); and personality names (registering the names of celebrities).

Initially, the DNS had no policy to cover trademark disputes. RFC 1591, the document enunciating policies with respect to domain name allocations stated only that "In case of a dispute between domain name registrants as to the rights to a particular name, the registration authority shall have no role or responsibility other than to provide the contact information to both parties" (Section 4(1), Postel 1994). However, Network Solutions as the domain name registry was concerned that trademark disputes involving domain name allocations may create legal liabilities for itself: consequently, a dispute resolution policy was framed in 1995 that required registrants to certify that they intended to use the assigned name, and that the name did not violate the trademark of third parties (Mueller 2002). Also, Network Solutions reserved the right to take back a name assignment in case of a dispute when a prior trademark registration existed (previously, assignments were considered to be final). Network Solutions was trying to transfer liability to customers, and minimize legal costs—and ended up privileging large corporations over small users.

Soon after its formation, ICANN too came under pressure to frame a dispute resolution policy with regard to trademarks. The World Intellectual Property Organization (WIPO) representing the intellectual property industries presented a report to ICANN advocating several steps to protect trademarks (WIPO 1999). Incorporating some of the WIPO recommendations, ICANN eventually

produced a Uniform Domain Name Dispute Resolution Policy (UDRP) that all registrars agree to implement as a formal requirement for accreditation (ICANN 1999). As was the case with the Network Solutions policy, registrants are held responsible for ensuring that domain name registrations did not violate any pre-existing trademarks: in addition, the UDRP framed administrative dispute-resolution procedures. Any third party may bring a dispute to ICANN if "a domain name is identical or confusingly similar to a trademark or service mark in which the complainant has rights; and the (current user) has no rights or legitimate interests in respect of the domain name; and/or (the) domain name has been registered and is being used in bad faith" (Section 4(a), ICANN 1999). The case will be referred to an administrative dispute-resolution service provider, which the complainant chooses from a list maintained by ICANN. If the complaint is sustained, the domain name registration may be cancelled or transferred to the complainant.

ICANN's UDRP has been generally welcomed by trademark and intellectual property interests, but it has also drawn a fair share of criticism. Froomkin (2002) for example has criticized the UDRP on both procedural and constitutional grounds: he argues that it tilts the process too much in favor of trademark interests and against individual users, and leads to the usurpation of the law-making function by a private corporation using its control over a vital Internet chokepoint. Geist (2002) examines cases arbitrated under the UDRP and finds considerable evidence of "forum shopping"—plaintiffs have used their right to choose the arbitration service provider to steer cases towards complainant-friendly courts, leading to a disproportionate number of judgments against registrants.

Creation of New Generic Top-Level Domains

One of the main responsibilities of ICANN as the custodian of the DNS root is to determine whether new generic TLDs need to be created, and to speedily create them whenever the need exists. However, attempts to add new gTLDs have repeatedly run into opposition from trademark interests who allege that new top-level domains increase the opportunity for unscrupulous third-parties to indulge in practices such as cybersquatting. To prevent such abuses, trademark interests have often registered their marks in multiple domains as a way of preempting malicious registrations—the addition of new TLDs, they allege, would impose additional costs of registration and monitoring on trademark holders. Thus, a recommendation against the creation of new gTLDs was a part of the WIPO Report submitted to ICANN in 1999 (WIPO 1999).

However, as several observers have argued (Mueller 2002; Pare 2003), restricting the number of new top-level domains creates an artificial scarcity in the domain name space that increase the value of existing registrations, and ironically provides an incentive for cybersquatting. But in spite of the increasing demand for new gTLDs, ICANN has expanded the original list only twice since 1998, the latest expansion bringing the total number to nineteen (see Table 1). Currently, ICANN is engaged in a public comment process to develop a policy framework for the introduction of new gTLDs: some of the questions under

discussion include the framing of criteria to determine whether new gTLDs need to be added, procedures for the selection of TLD names, allocation methods to choose TLD registries, and the contractual obligations of ICANN and registries/registrars in the new domains.

Relationship with Country Code TLDs

Although ICANN was able to conclude registry agreements with Network Solutions/Verisign and other gTLD registries relatively easily with the backing of the U.S. government, it has faced more significant problems in bringing the ccTLDs within its sphere of oversight. The lack of any international treaty conferring legitimacy on ICANN, and the perception that it is a creature of the U.S. government has made international entities such as the ccTLD managers and the regional Internet registries (RIRs) managing IP address allocations less keen to submit themselves to ICANN oversight.

ICANN wanted ccTLD registries to be bound by the same responsibilities as the gTLDs under the registry agreements: however, country governments wanted to choose registries and registrars for their ccTLDs themselves, and to have policy authority over their own national Internet space. This conflict was especially acute when ccTLD registry functions needed to be transferred from one entity to the other. ICANN's original policy stated that ccTLD registry functions could be transferred only by consensus: "(IANA) must receive communications from both the old organization and the new organization that assure the IANA that the transfer is mutually agreed" (Section (e), Transfers and Disputes over Delegations, of ICANN policy document ICP-1 1999). However, national governments with coercive powers over their citizens have less need for consensus, and can take decisions unilaterally. As reported by Feld (2003), in South Africa, the government "acted unilaterally to assume control of its ccTLD, .za, through the expedient of making it a crime to operate the .za ccTLD except in a manner prescribed by the South African government" (p. 354).

Currently, an agreement crafted in ICANN's Government Advisory Committee (Principles and guidelines 2005), clearly establishes that the national government has the right to name the ccTLD registry: "ICANN should delegate the administration of a ccTLD only to an organization, enterprise or individual that has been designated by the relevant government or public authority" (Section 7.4). As of this writing, the vast majority of ccTLDs have not concluded a separate registry or sponsorship agreement with ICANN.

FUTURE OF THE DOMAIN NAME SYSTEM

So far in this article, the technical, institutional and policy aspects of the domain name system have been discussed. Though it is primarily a technical system, the importance of the DNS for the smooth functioning of the Internet has created tremendous public interest in its institutional and policy environment. Many aspects of the DNS are heavily contested politically, by both domestic and international interest groups and constituencies. A number

of challenges remain to be overcome. Several initiatives now underway are likely to have a long term impact on the future of the DNS and by extension, the Internet.

Transition to IPv6

Policy documents on the IPv6 transition had intended the process to be simple, incremental and flexible by specifying four basic requirements (Bradner and Mankin 1995): that existing IPv4 hosts and routers should be upgradeable at any time without any other hosts or routers being upgraded; that new IPv6 hosts and routers could be installed at any time; that existing IPv4 hosts and routers may continue to use their existing addresses after being upgraded to IPv6; and that both upgrades and new IPv6 installations should be low cost, and involve little or no preparation work. In spite of these built-in precautions, IPv6 deployment has been slower than expected. A survey of local Internet registries (LIRs) to which IPv6 allocations have been made identified some of the reasons: absence of vendor support; low consumer demand, and lack of a "killer application" that requires the features available only in IPv6 (RIPE NCC 2002). Concerns about privacy may be a problem too: since the interface identifier portion of the IP address remains constant to enable autoconfiguration, it becomes possible to track the location and usage of a particular device (Euro6IX 2005). Cost is another factor—as one recent news report stated, the U.S. government alone may have to spend as much as \$25 to \$75 billion for a full transition to IPv6 (Kerner 2005).

In spite of the potential hurdles, it is evident that IPv6 deployment is only likely to accelerate as the problem of address scarcity becomes more acute. This is evident from the fact that more IPv6 prefixes have been allocated in Europe and Asia than in North America, including the United States (RIPE NCC 2006). Because proportionally more IPv4 address blocks were assigned in the United States in the early days of the Internet, the problem of address scarcity has been felt more quickly in Europe and Asia, resulting in quicker uptake of IPv6 address blocks.

Alternative Name Systems

Periodically, there have been attempts to set up competing domain name systems (called alt roots) in competition with the DNS, with their own root servers and top level domains. For example, several small Internet service providers came together to create the enhanced domain name service (eDNS) in 1997, with top-level domains such as .k12 for children, .npo for non-profit organizations, and .corp for corporations (Denninger 1997; Mueller 2002). Other alt roots include the Open Roots Server Confederation (ORSC) (www.open-rsc.org) and Open DNS (www.opendns.com). Most of these alternative root systems are now defunct.

A recent report (SSAC 2006) identified some of the reasons why alternative root systems continue to be attractive to some Internet stakeholders. Private name systems are sometimes set up by private networks for internal communications. Some commercial name system administrators may want to profit from registering names in new TLDs over which they have full control. Others may support alt root systems to signal dissatisfaction and to protest

against the slow process of defining new TLDs by ICANN. National governments, distrustful of the U.S.-centered governance model embodied in ICANN, may want to support alt root systems to gain better control of the national domain name space, to remedy insufficient root server support in their territories, or to support domain names in local linguistic character sets. For example, official Chinese sources first announced (and later denied) that the Chinese government has set up its own top-level domains permitting the use of Chinese characters (Bray 2006a; 2006b). The reported reason was frustration at ICANN's lack of progress in creating non-Latin character domains.

Alternative root systems have major implications for interconnection and stability on the Internet. Because domain names listed with an alt root system would be invisible to the rest of the Internet unless listed in the dominant root system (the DNS) as well, the rise of alt root systems threaten to split the Internet. However, there are strong self-reinforcing "network externalities" inherent in root server systems—network administrators would "point" their name servers at the root system with a larger number of listings, and registrants would prefer root systems with more name servers pointing to them (Mueller 2002). This need to "see" and "be seen" would perpetuate the dominance of root systems with a larger number of domain name listings. It is very difficult for alternative systems to survive unless a critical mass of Internet stakeholders (registries, ISPs, users) simultaneously shift allegiance. Technically, alternative root systems may co-exist with the dominant DNS if domain name registrants list their name in both the dominant DNS as well as in alt root systems; or if root systems "point" to one another to resolve unknown addresses. But dual registrations are unlikely because of the burden of registration fees and transaction costs, and cooperation between root systems is hindered by animosity and lack of trust. The emergence of an alternative system at present seems unlikely.

Although this appears to assure the continuing dominance of the DNS, there is a possibility that alternative root systems could be set up in the future especially if dissatisfaction with ICANN continues to mount. The root could be fragmented if, for example, an alliance of national governments, opposed to the special relationship of the U.S. government to ICANN, decides to promote up an alternative root system. Internationalizing domain name governance is thus a pressing priority.

Internationalizing Domain Name Governance

The Domain Name System enjoys a rather unique role as an emergent form of international cooperation. Traditionally, activities that span national borders have been conducted under the aegis of states, or of international organizations created through treaties between states. On the one hand, ICANN has been heralded as a new type of international organization, a path-breaking "private-public partnership" with global reach (ICANN 2004); an emergent "international regime" (Mueller 2002); "private ordering" (Schwarcz 2002), etc. On the other, ICANN has been criticized for the insularity and 'clubbiness' of its board of directors, the opacity of its decision-processes,

the uncertainty about the values ICANN seeks (or should seek) to promote and the lack of meaningful outside appeal of its decisions (Froomkin 2002; Mueller 2002; Schwarcz 2002; Pare 2003; Weinberg 2000).

A recurrent theme of criticism is also that a decision-maker like ICANN whose influence spans the globe functions under a contract with the U.S. government. Though the U.S. government has often stated that its policy goal is to preserve private management of the DNS, several recent events have demonstrated that the U.S. government continues to exercise significant influence over ICANN's decision-making. In one such instance, ICANN in June 2005 initially approved a new TLD for adult content tentatively labeled .xxx (McCullagh 2005), but reversed itself in May 2006 by blocking it ("Internet agency nixes '.xxx' Web addresses", 2006). ICANN's Paul Twomey explained that the .xxx domain was rejected because ICANN did not want to become the enforcer of all national pornography laws. Though many foreign governments and private citizens too had objected to the new TLD for pornography, critics alleged that the main influence on ICANN was a letter from Michael Gallagher, assistant secretary in the U.S. Department of Commerce (Gallagher 2005).

It was for this reason that proposals like the gTLD-MOU have periodically surfaced to put Internet governance on a clearer international footing. The most recent of these initiatives is the dialog on Internet governance under the aegis of the World Summit on the Information Society (WSIS). The United Nations General Assembly resolved in 2001 to create an organization to promote a "people-centred, inclusive and development-oriented Information Society" (Section A(1), WSIS 2003). Accordingly, two summits of the WSIS were organized, the first at Geneva in December 2003, and the second at Tunis in November 2005. The issue of Internet governance gained prominence in the preparatory meetings to the Geneva WSIS summit: key concerns centered on the creation of a suitable international organization, support for a multilingual Internet and national sovereignty over each country's domain name space (Kleinwachter 2004). The final Declaration of Principles of the Geneva WSIS reflected these concerns calling for Internet management to be "multilateral, transparent and democratic, with full involvement of governments, the private sector, civil society and international organizations" (Art. 48); to be supportive of multilingualism (Art. 53); and to render assistance for developing countries (Art. 63) (WSIS 2003).

However, neither the Geneva Summit nor the parallel deliberations in the ITU Plenipotentiary Conference at Marrakech (1992) was able to bring about substantive changes in Internet governance: the final compromise was to agree to disagree, and to postpone the issue to the second WSIS in Tunis in 2005 (Kleinwachter 2004). To prepare a set of formal proposals for Tunis, a Working Group on Internet Governance was set up by the U.S. Secretary General. Its final report recommended that "no single government should have a pre-eminent role in relation to international Internet governance" (Section V, A(2), Working Group on Internet Governance 2005 p. 10). Four separate governance models were proposed for consideration, all involving a greater role for national governments in either an oversight or a policy-making capacity.

Meanwhile, the U.S. government, concerned about the internationalization of the DNS, produced a statement of principles asserting its intention to “maintain its historic role in authorizing changes or modifications to the authoritative root zone file” and supporting ICANN as “the appropriate technical manager of the Internet DNS” (NTIA 2005). This statement was seen by many as a preemptive shot-across-the-bow to forestall any moves at the WSIS or ITU to assert oversight over the DNS root. The same intention was also reflected in a “Sense of the Congress” resolution passed unanimously (423-0) in the U.S. House of Representatives (H. Con. Res. 268, passed November 16, 2005) stating that “the current structure of oversight and management of the Internet’s domain name and addressing service works” and “therefore the authoritative root zone server should remain physically located in the United States and the Secretary of Commerce should maintain oversight of ICANN(.)” U.S. mainstream media too were generally supportive of the U.S. position: one national newspaper editorialized that the WSIS-ITU initiative was motivated only by anti-Americanism, a “reflexive” commitment to international governance, or Internet censorship (Puddington 2005). Though critics argued that the U.S. government’s assertion of an “exceptional role as unilateral contracting and oversight authority for ICANN” (p. 2) was directly contradicting its own White Paper policy (Mueller et al., 2005), the overall consensus within that country was in favor of continued U.S. Department of Commerce control over ICANN.

These competing influences came to a head at the Tunis WSIS summit. Eventually, a compromise was negotiated preserving the status quo fundamentally unchanged, but authorizing the creation of an Internet Governance Forum with “no power beyond the ability to bring together all the ‘stakeholders’ in the Internet, from consumer groups to governments to private business” (Shannon 2005, p. 2). The structure, procedures, and policies of the forum are currently being debated (see for example, Mueller and Mathiason 2006).

The outcome of the WSIS debates on Internet governance was seen as a major victory for the U.S. position. But with the majority of Internet users now residing outside the United States, this victory may be temporary and calls for the internationalization of Internet governance are likely to recur in the future. Apace with the technical improvement of the system, the Internet community also needs improve the institutional and policy aspects of DNS management to make it more transparent, participative, fair, and internationally legitimate.

INTRODUCTION

Information retrieval research and development cuts across many disciplines that include cognitive science, human-computer interfacing, information science, and linguistics and has long been considered a fundamental part of computing. Through Web-based search engines, information retrieval has become a mass consumer item and a large and sometimes lucrative business. But what precisely is meant by information retrieval? For this chapter an appropriate dictionary definition of information is “knowledge acquired in any manner; facts, data; learning; lore” implying that information can take any form including the text, images, music, or multimedia content common to the Internet. Definitions of information retrieval are numerous and exist in part as a result of the shared interest by the many disciplines concerned with acquiring, storing, and discovering information. However, the term information retrieval has generally come to be applied to such content that lacks a predefined structure and must then be modeled (by keyword, color, rhythms, and so on) in order to determine the content relevant to a particular query.

Internet IR is distinguished by the connection of an unparalleled number of information sources. Internet technology has at a minimum changed the scale and scope of information retrieval but promises more fundamental outcomes. Information has played a critical role in human development, a role that has often been focused and magnified through technology. The importance of information technology cannot be overstated as historically technology has determined whether information has been limited to the few or many, whether spanning geography and time. Writing, as an information storage technology, gave those with the means access to information from those they might never directly meet. Writing provided long-term information storage and retrieval, books collected and stored information on related topics and libraries were established to systematize storage and retrieval of books. The printing press revolutionized society; by reducing book costs literacy rates increased to give an average person access to information outside

their personal experience. The press did not produce any new information but merely encouraged sharing information by being more rapid, cheaper, and available than previous technologies, a technology that merely made information retrieval—in essence—easier.

Print and the Internet each support the collecting and sharing of information, but Internet technology provides two additional abilities. Where printing promoted literacy which increased the consumption of information, the Internet has made everyone a potential producer—where print created mostly disconnected islands of information, the Internet has created the potential of a single large collection. The intersection of these two capabilities make Internet information retrieval unique and important as for the first time in history a major portion of the world’s information is instantly available to a large number of individuals. Although Internet technology creates the collective information pool, the challenge is locating the right information to retrieve.

This chapter is primarily about that challenge—how to find the right information—providing an overview of the approaches currently employed. The chapter focus is then Internet IR technology, meaning those systems that would not exist without the massive number of information sources the Internet provides. Those information types considered include the most common on the Internet—text, images, audio, music, video, and multimedia. Purposely limited from close examination are many important IR systems that happen to be accessed over the Internet, but do not effectively utilize the information collection created by the Internet structure. Such systems do not depend upon the high degree of interconnection or great number of potential information sources available through the Internet.

The Internet has been a remarkable vehicle for IR development. Because Internet IR depends upon such a large and diverse set of technologies that range from search algorithms to mobile devices to server architectures to user interfaces and beyond, some choice of topics and depth of coverage have been necessary in organizing the chapter. As the most familiar and successful contemporary example of an Internet IR system, the text search

engine is discussed in some detail serving as a model for discussing IR of other media. Although IR for each media type will be examined, a short overview now of some key points will be helpful later.

IR system technology can be viewed as having two main parts, the interface used by the searcher to query the retrieval system and that part concerned with organizing and retrieving the information. In systems such as the text search engine the two parts are very loosely coupled and user control strictly limited. Text search engines and browser text boxes for queries form the predominant IR system of the Internet. But searching other media presents a very different set of problems that require very different retrieval techniques depending on whether the information form is text, images, audio, metadata, or some combination. User interfaces can also provide a richer set of tools to control search and assist in organizing the results into meaningful information.

One key characteristic possessed by text versus other media is semantics or that each individual word has meaning. Words are also easy to index, for users to create queries and for retrieval; users can also understand and use the results in refining their next query. Other media, such as images and audio, consist of many low-level features that only when combined and synthesized can be understood to have meaning. For example, at low-level, digital images may contain millions of differently colored pixels but at a higher-level, that of semantics, these pixels represent a friend or for a group of audio features, a song. Non-text media is also of much higher dimension, there are many features that define an image, such as color, texture, and shape, which must be distinctively encoded and indexed for efficient retrieval over large, Internet-size collections. Formulating queries in a non-text media has often been limited to low-level feature (e.g. colors) examples for retrieving similar media or text when semantics could be inferred from the media. Combined, these differences help explain why text IR is a key technology on the Internet while there are currently few Internet-scale non-text IR systems. Even though none have achieved the functional level of text search engines, research and development progress has been significant and continuing.

The chapter is organized as follows. As the most familiar, intuitive, and developed of IR systems, text search engines are examined first and most extensively while providing a foundation for separately exploring other media types and systems. Because IR systems are also tools for exploring information, user interfaces that support discovery of information are a critical part of the system. The retrieval technology and user interface will generally be reviewed in context as a complete IR system to better understand their interaction. However, exploratory search, a distinct search strategy of importance particularly for large information collections, will be examined separately. The reader should also be aware that Internet text IR as exemplified by the search engine is comparatively mature and commercially established but IR of other media and other approaches, although many examples exist, is still much in the realm of research.

TEXT INFORMATION RETRIEVAL

Text IR, as exemplified by search engine sites such as Google, is arguably the most common, economically successful and technically mature of the Internet IR. An examination of text IR and search engines can provide the fundamentals necessary to understanding Internet IR in general; hence, we will examine common text search engines first and in greater detail and apply those lessons to understanding other approaches and media.

What explains the success of search engines? For technical reasons examined later, text is simpler to search than other media such as audio or visuals. Much of Internet text IR is Web-based and involves three participants: the searcher, the search engine site, and the information source, a Web site. The Internet IR and Web development has been strongly influenced by business models based on text that is generally available for free as compared to commercial audio and visuals. Web sites generally post free text for self-promotional reasons, whereas audio and visuals are often produced at considerable cost for explicitly commercial reasons. One can argue that text search is successful to a large degree because a common interest is served where the information searcher, search engine, and Web sites each derives benefit. It is useful to keep in mind that the searcher is the only reason for Web sites and search engines to exist and is then in the interest of each to satisfy the searcher's needs.

The searcher, search engine, and Web site then comprise an IR system that to fully examine, we should and will consider each in turn. Examined first will be searcher issues that include the recognized types of search strategies and measures of performance followed by the workings of a typical search engine and concluding with the Web site holding the information, how to establish what search engines search, and how to manage or influence search engines to a Web site's benefit. Although IR has a strong technical element, IR serves human activities that are directly influenced by human perceptions; the discussion will necessarily include a mixture of technical and non-technical topics.

Developing a broad perspective of the text search process is useful before a detailed examination of individual components begins. Figure 1 illustrates the characteristic interaction between the three partners in information search and retrieval. First steps of the process typically begin by submitting the Web site's main page URL to the search engine or when the site is otherwise discovered. The typical search engine architecture (Arasu et al. 2001) consists of two main parts; one component called a spider (or crawler, robot) visits the Web site to retrieve pages linked from the main page much as a person using a browser would follow links to new pages. The spider follows links, indexing meaningful words from the retrieved pages which are stored along with the page's Web site location for later searches and retrievals. The second component of the search engine interacts with the searcher by providing a user interface for the searcher to query the search engine and receive back a list of relevant Web site page locations from which the searcher can select and retrieve pages directly from the Web site. Closing

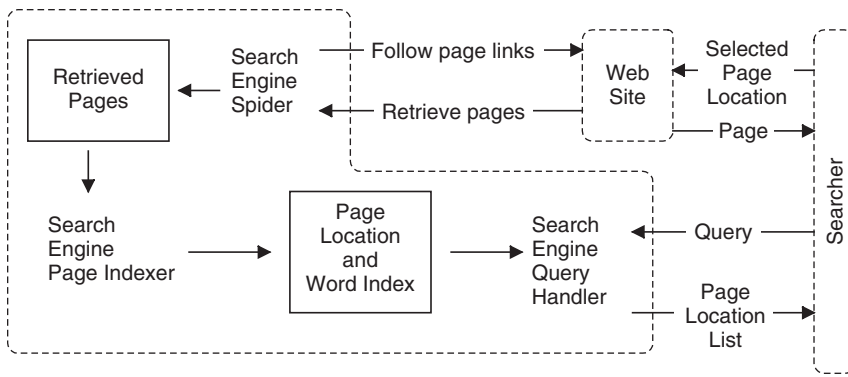

Figure 1: An overview of a search engine and its relation to Web sites and information searchers. The basic steps to Web search are as follows: a search engine spider visits a Web site to retrieve and index pages into a database for later searches; the searcher sends queries to the search engine; the search engine locates pages containing text similar to the query and sends the searcher a list of page locations; the searcher selects and retrieves pages from the Web site.

the information space between the searcher and Web site is then the primary purpose of the search engine.

The IR system implemented by a typical text search engine is relatively technically simple, but, unlike most non-Internet IR systems, involves three separate entities each with differing and sometimes conflicting goals for IR. To separate one from the other, the following sections examine this system from the three different points of view of the searcher, search engine, and Web site.

Searcher Issues

Why search? A simple answer is that the Web is too large and unorganized to find much useful information by simply employing a manual browsing strategy that follows links from one page to another. Describing the growth of the Internet and the Web would seem an exercise in hyperbole but for the fact that it is astounding. By 1999, public sites already contained about 800 million pages on about 3 million servers (Lawrence and Giles 1999), by 2005 it was estimated to have grown to 11.5 billion pages (Gulli and Signorini 2005). The number of Web sites exceeded 100 million in November 2006 (Netcraft.com 2006), an increase of over 30 million in a single year.

The purpose of the original Web design was simply to interconnect bits and pieces of scattered information with no plan to find information other than by manually browsing from one piece of information to another via connecting links. To some degree, search engine systems merely automate the process and move faster from one piece to the next than users do while collecting information along the way for later retrieval. Web site usability studies recognize search as one of the most important means for finding information (Nielsen 1997). Although Web pages generally provide specific navigation choices, more than half of all Web site visitors navigate predominantly by search and use search as their first choice to find specific information. Many usability experts argue that search is so important it should be available from every single page on a Web site. Part of that rationale for search is that once visitors navigating connection links get lost they will need search and should not have to search for a search page.

Types of Search

Search often fails to some degree; even though the information may be available in the IR system, searcher strategies

may not be compatible to produce optimal results. For the IR system designer interested in identifying good search strategies it is worthwhile to consider the different types of search and how search engines align with different strategies. Information retrieval experts (Rosenfield and Morville 1998) recognized four ways in which people search.

Known-item Search: A search engine is not always necessary. Searching a brokerage site for the latest stock quote is one example. The information sought is unique, is easily recognized when found, and often exists at known Web sites. Searching, if any, is short and direct and the answer immediately recognized. Search is unneeded if the information location remains fixed, even as the information changes. The search can be restricted to specific sites, reducing search time and improving the information quality.

Existence Search: Appropriate when prior knowledge of a subject exists. For example, existence search can easily discover cases of plagiarism, such as where some part of one site has been copied to another. However, consider the difficulty in searching for something that may not exist. Suppose that someone who needed to organize phone number lists, notes, and appointments had never heard of a personal digital assistant (PDA). The person would know the needed function but not where to look or that a PDA even existed. Search can meander as users discover and digest information; even recognizing the answer when found may be difficult. Web search engines are a natural choice for determining whether information exists because they attempt to find all available information on the Web. Entering a few well-chosen query words to a search engine will search millions of pages and can produce thousands of pieces of information. One gap in existence searching is that search engines cover only a fraction of the Web; the more obscure information can exist on parts of the Web never visited and hence unknown to the search engine.

Exploratory Search: An iterative process of acquiring subject knowledge by collecting and integrating information that leads to further exploration. This is the case when the user knows that the subject such as a PDA exists, but does not know exactly what a PDA can do and needs to learn more. Uncovering and comprehending the information may be long and circuitous; recognizing

the answer may not be immediately possible due to the lack of subject knowledge. One productive search strategy is browsing information organized into subject lists with main subject areas and a breakdown into finer categories of related subjects.

Comprehensive Search: This type of search is best suited when users know the search subject, can recognize the answer when found, and need all available information on the subject. For someone with a general knowledge of PDAs, buying a PDA requires comprehensive information on several brands, models, and suppliers to make an informed decision. Web search engines work well for comprehensive searching of the entire Web but for broad subjects such as PDAs can produce an overwhelming volume of information.

Text IR as currently practiced on the Internet can be further lumped into the two broad types of analytical and exploratory search (Marchionini 2006). The common search engine supports analytical searches, those that are primarily a direct look up based on existing knowledge of the information sought. Exploratory search is not well supported by the search engine model. Exploratory search places the user more in control of the direction and pace of search, providing organization, cues, or other guidance to create an uninterrupted exploration guided by human participation. A variety of exploratory search models have been developed, many visually illustrate information relationships in spatial dimensions, and many include elements of text mining to reveal those relationships. Although search engines support only analytical search directly, alternative approaches often incorporate search engine results for implementing other forms of search and other media than text; several of these will be discussed in the following sections.

Information Sources

Most successful information searches fail to some degree on the first attempt. Other than the known-item search, most searches evolve to use several search strategies as one attempts to iteratively improve the relevancy of information retrieved. Though the term search engine is often applied to any Web-based information source, there are at least two main types of Web information sites: those that automatically organize information and those having human-organized lists. Many information sites provide a mixture of the two following approaches.

Lists: Catalogs, directories, and lists are similar examples of human-organized subject indexes of Web-based information. A list arranges subjects into a hierarchy that allow exploration from a general topic, such as "education," down to the more specific subtopic of "graduation poems." On most lists, humans index the subjects providing control and intelligence to the subject hierarchy organization, arguably yielding less but higher quality information than current automated cataloging systems. The hierarchical approach works well for exploratory search when one is familiar with the search subject and has a good sense of how the subject fits within the hierarchies of a larger subject.

Finding a subject in a hierarchical list can be difficult when the searcher's idea of subject organization differs from that of the person creating the list. For those cases, a keyword query can search the subject list as a way to pierce an opaque subject hierarchy; a query such as "graduation poems" will generally locate the same information as manually moving through the "education" subject hierarchy. If the query fails, many list services automatically send the query to a Web search engine.

Although information sites consisting mainly of human-organized lists or automated searches are often lumped together as search engines, how each gathers and represents information is quite different. Human-organized lists depend upon editors to first review Web site pages and organize the collected information into subject hierarchies. A searcher can then manually browse a subject hierarchy list to find information. Lists more accurately reflect true page content than automated searches because human editors do not review the parts of a page not normally seen by a reader and can ignore gratuitous or repetitive words used to attract a search engine. One weakness of lists is the effort required of the editors to perform the review. After a site review is completed, significant changes to the site content are unlikely to prompt another review, although most lists do accept site resubmissions.

Search Engine: A search engine essentially matches query words with words on Web pages and lists the pages containing the matching words. Entering the query word "zucchini" returns a list of pages containing the word "zucchini." In practice, Web search engines examine pages drawn from across the Internet to automatically calculate measures to rank pages in order of some specified information relevancy. Determining a meaningful page rank based on a few query words is challenging and sometimes produces completely irrelevant results. Entering the single word "zucchini" will find any page mentioning "zucchini," from gardening to cooking to diet; which "zucchini" page is important is ultimately in the mind of the searcher. Determining how to rank one document against thousands of others is a key point of competition between search engines and often the identical search on any two will produce different results, searchers may need to consult several to have confidence in the results. Metasearch engines automate searching on multiple sites by sending the search query to a number of search engines and creating a fusion of the results. Overall, search engines are best suited for existence and comprehensive types of analytical searches where the relative quantity of information retrieved is important.

Measuring Performance

Ideally, a search engine result includes all relevant documents, ranked in order of relevance. Search engine performance can therefore never be perfect as the Web is indexed incompletely and relevancy is highly subjective.

Several definitions of search performance common in the literature are: "relevancy," "recall," and "precision." Relevancy measures the usefulness of the references retrieved, is subjectively determined, and may vary as searching and knowledge acquisition of a subject evolve.

Figure 2: Retrieved versus relevant pages when searching the Web. The intersection of retrieved and relevant pages will likely be relatively small in part because only a fraction of the Web is indexed

Figure 2 illustrates three useful points: (1) that relevant references are generally a subset of all the references available; (2) that retrieved information generally includes some irrelevant references; and (3) that the intersection of retrieved and relevant references will often exclude references that are relevant (van Rijsbergen 1979). The following definitions of *recall* and *precision* complement the intuition illustrated in Figure 2:

$$\text{recall} = \frac{|\text{retrieved} \cap \text{relevant}|}{|\text{relevant}|}$$

$$\text{precision} = \frac{|\text{retrieved} \cap \text{relevant}|}{|\text{retrieved}|}$$

Recall is the percentage of relevant references retrieved. A recall of 50% means that only one-half of the relevant references were retrieved; retrieving every possible reference yields 100% recall but often includes many references that are irrelevant. Precision is the percentage of retrieved references that are relevant. Of the references retrieved, a precision of 50% means that only one-half of the references were relevant; returning only one relevant reference yields 100% precision but possibly very poor recall. A “weight loss” query can yield perfect recall by retrieving every Web page in existence but will likely produce many that are not relevant, so that precision is poor. Simultaneously achieving perfect recall and precision is nearly impossible even when searching carefully designed and constructed sets of known information.

Performance Measures

The three most common performance measures are recall, precision, and ranking. As discussed, *recall* is defined as the percentage of relevant pages found and *precision* as the percentage of pages found that are relevant. A search engine calculates *rank* to measure relative page relevancy, using individual page rank to order the pages from less to highly relevant. As a way to gauge individual search engine strengths and weaknesses, the following describes searches that provide observations of these three measures.

Recall: Searching for something one knows is on a Web site gives a rough estimate of recall. If a user’s name appears in Web pages on his or her site, searching on that name should return results from the site and perhaps

other sites as well. If recall is 100 percent, restricting the search to the user’s specific site should return all pages on the site containing the user’s name. For testing recall, the Google search engine query “vegetarian site: www.eatmorevegetables.com” should return all pages with the word “vegetarian” from the fictitious site “www.eatmorevegetables.com.” Most search engines follow only a limited number of page links on a single site, stopping at some maximum number of links deep. Searching for pages several links deep from the site main page then measures the search engine’s recall ability. If one-half of the relevant pages on a site are found, recall is 50 percent and indicates that the search engine spider stopped after following some arbitrary number of links from one page to the next.

Precision: Precision is difficult to mechanically quantify as it measures the number of relevant pages among those found and relevancy is by nature subjective. Because search engines generally list only pages that contain matching query words, precision is always arguably high. However, when users find thousands of pages and only a few are relevant to their needs, the challenge is to focus the search on more relevant and generally fewer pages. The searcher can influence the search precision by including or excluding query words, limiting the search to known sites, or using other search controls. Searching for a known page can test the degree of search control and precision afforded by a search engine. Most search engines provide sufficient control to limit the results to a single page. For example, on some search engines the query “vegetarian diet” would find all pages with “vegetarian diet” anywhere in the page whereas the query title: “vegetarian diet” would find only pages with that phrase in the page title. The more refinement afforded by the search controls, the better the search precision possible.

Rank: Rank reflects the calculated relevancy of a document. One key factor determining rank is the number of query words matched in a page; generally the more words matched the higher the rank. Matching rare words also increases the rank of the page. Search engines can also employ the structure of the Web to improve relevancy based on links to and from other pages to augment the ranking of pages. Pages with many links from other pages generally rank higher than pages of equal similarity to the query but with fewer links.

Page popularity and importance are two common ranking measures based on link structure. Popularity assigns a higher rank to pages having more references from other pages, under the assumption that a frequently referenced page is more relevant than a page with fewer references. However, a popular page is not automatically important. Page importance further assumes that pages or sites that mutually refer to one another form groups of importance or authority on a subject. The more references to a page from others in the group, the greater the importance and consequent rank of the page. The resulting groups are somewhat analogous to the subjects of a list service with the exception that humans organize subject lists and the interconnecting references organize a group. Automatic grouping can produce more focused and higher quality references but eschew the hierarchical organization that supports browsing of subjects by the searcher.

Which ranking approach produces the best result depends upon the user's search needs. Comprehensive search is the natural outcome of search based on word match ranking alone but yields no organization of the results. Existence and exploratory search can benefit from the reference-based ranking methods of popularity and importance. Popularity ranking anticipates that the information that many others reference represents common knowledge of a subject. Importance attempts to refine popularity ranking by organizing references into supporting groups. Grouping together documents that have common references will generally provide more homogeneous results and is best suited for exploratory search in which the subject is recognized.

Search Control

The user interface is a key component of any system involving humans, in the case of an IR system, the user interface provides the searcher the means of controlling the search process. User interfaces for the major search engines are a model of simplicity and appropriate for analytical searching. Text IR on the Internet, by almost any measure, has been a success in part as a result of this simplicity and intuitiveness in which the searcher and search engine interact through a straightforward turn-taking relationship of sending queries and receiving a linear ranking of results. Key is that the search model employs text to find text allowing the searcher to compose a simple example query in text to search for documents having matching text. This uncomplicated user interface is possible in large part because the searcher has a well-developed knowledge of the semantic value of the words used in the open-ended queries and in the returned results. It should be noted that although the searcher is keenly interested in the semantics of the query and results, as will be seen in the next section, the typical search engine makes little use of semantics.

An important element of IR user interfacing is feedback that indicates not only some measure of search success but also reflects an obvious relationship between the query and results. The feedback provided by the search engine is often a linear, ordered ranking of search results relating the query words with the text in which the words were matched. Because the search engine makes little if any use of query or document semantics, the results are strongly influenced by query word occurrence within the document. Given that search engines are tuned to achieve a high degree of precision for the first few page results and high recall for subsequent pages, result lists can consist of several thousands of matched documents. Although the feedback is critical to refining future queries, the feedback provided is often too great and not always clearly related to the initial query as to be helpful in refining future queries.

Fine control of search queries to yield higher quality references is possible in theory and is provided in some form by most search engines. The more common search controls include ones similar to those below.

Adding Search Terms: Adding search terms to the query can improve the precision of search results. The

query "weight loss" produces millions of pages with each containing the word "weight," "loss," or both. Adding terms for "vegetarian weight loss diet" produces merely 10,000 but more focused references. Each page found still contains at least one or more of the query words. Because search engines generally rank pages higher that match more query terms, pages with fewer discriminative terms are effectively ignored.

Phrases: Queries consisting of phrases can yield more precise results than the same words when matched independently. A query of the phrases "vegetarian diet" "weight loss" produces only about 3,000 page references, of which the highest ranked pages contain both of the two phrases.

Inclusion and Exclusion: Query words prefixed with a "+" are words that must be included or found on a Web page, whereas words prefixed with a "-" must be excluded or not occur on the page. The query "+diet-vegetarian" then means that "diet" must be found on the page and "vegetarian" must not be found. The Boolean operators AND, NOT, AND NOT are often used alternatives to the "+" and "-" operators. The query "diet AND NOT vegetarian" is normally equivalent to our earlier query. The OR operator matches either term; "weight OR mass" matches "weight" interchangeably with "mass."

Proximity: Limiting matches to only words or phrases occurring within a close proximity to another assumes that nearness implies some relation between the words. The query "vegetarian NEAR diet" would find pages having "vegetarian" within a few words of "diet" but exclude pages having "diet" distanced from "vegetarian" by more than the proximity word limit.

Wildcard: An "*" at the end of a word or partial word expands the range and number of matching words. For example, the query "veget*" finds pages that include "vegetarian," "vegetable," and any other words starting with "veget."

Field: Limiting the search to a designated field of the Web page, such as considering only pages available on a specified Web site, can greatly narrow the search focus. As an example, title: "vegetarian diet" requires "vegetarian diet" to be part of the page title field, whereas "site:food.com" limits the search to the "food.com" Web site pages. The link control lists all pages with a reference link to a specified site; the query "link:food.com" will list all pages that link to pages on the "food.com" Web site.

As already noted, the common search engine supports analytical searches, those that are primarily a direct lookup based on existing knowledge of the information sought, but does not support browsing of information necessary for rapid exploration of a topic for which little is known. Ideally, the user interface complements IR, adapting to the changing needs of the user as their search for information evolves. However, the typical user interface strictly limits user choices and control of the interaction possible between the search engine and searcher. User interfacing is more of an issue for IR of media other than text and other search strategies than direct search; a more general user interface discussion will be delayed for inclusion with other media and strategies.

Basic Search Engine Implementation

Automated search engines have two main tasks: organizing selected words from each page into an index and answering search queries from that index. Web-based search engines owe a debt to the foundational work on traditional full-text IR systems, such as the SMART and SIRE systems discussed below (Salton and McGill 1983) to present a foundational and somewhat simpler perspective of their operation. In place of human editors to extract and index subject information from pages, such systems perform automatic indexing of complete pages into an inverted index database containing lists of words and the corresponding pages that contain each word. In answering queries, the search system compares query words to page words from the index, retrieving those pages that have a high calculated similarity to the query.

Indexing

Selected words of a page have a weight factor calculated based in part on word frequency. Weight measures may also give greater or lesser importance to words in different parts of the page; for example, title words generally receive more weight than regular text words. A word that occurs in few pages also has a higher weight, based on the proportion of times that the word occurs in a single page relative to all other pages. A word that occurs on only one page would have relatively high weight, whereas a word occurring on all pages would have low weight, the rationale being that a rare word is more useful in finding a specific page than a word common to many pages.

The same rationale applies to the removal of stop words such as conjunctions and pronouns that convey little meaning due to the high frequency of their use. Note that stop words may also be indexed for comparison with user queries consisting of phrases containing stop words such as "The Statue of Liberty." Stemming is an additional method used to minimize the number of unique words retained by converting all word forms to some base form. A simple stemming algorithm may only convert plural to singular form while a more aggressive stemming algorithm might additionally convert *vegetable* and *vegetarian* to a common stem of *vegeta*.

Conceptually, a simple two-dimensional matrix is constructed (commonly known as a term-document matrix) containing the calculated weight of each remaining word on each page; pages define one dimension and the other dimension defined by the words remaining in that page after stemming and stop word removal. In fact, an inverted index is often generated that contains all remaining words from all pages; included with each word is a list of all the pages that contain the word. For each page in the list, there is stored the frequency with which the word occurs in the page for weight calculation and the external location of the page for later retrieval.

A variety of methods exist to quantify the importance of a given word in a given document (page). Documents (pages) can be represented by a weighted vector of terms (words) as

$$D_i = \langle t_j, w_{ij} \rangle$$

in which w_{ij} represents the weight of term t_j in document D_i and non-existent terms in a particular document have a weight of zero. Queries can be represented similarly as

$$Q_i = \langle t_j, w_{ij} \rangle$$

The weight of each term depends upon its frequency of occurrence in the document and the number of documents in which it appears. The weight of a term is then given as

$$\langle w_{ij} \rangle = tf_{ik} \times idf_k$$

in which tf_{ik} is the number of occurrences or term frequency of term t_k in document i , and idf_k is the inverse document frequency of the term t_k in the collection of all documents. Among the simpler of the numerous inverse document frequency definitions is

$$idf_k = \log(N/n_k)$$

in which N is the total number of documents in which n_k have occurrences of t_k .

Note that Web search engines must differ significantly from traditional search engines because of the large number of pages that are scattered across many thousands of Web sites and that each page can have connecting links to many other pages. To find pages and build the index, the indexing program must then visit Web sites as one would with a browser, starting at a page, visiting connected pages, and indexing each page as it goes. In the jargon of the Web, a spider, robot, or Web-crawler is the program that visits or crawls connected pages, indexing selected parts from the visited pages. The resulting index contains the word lists of traditional text searching and the unique location of the page for retrieval. For each page indexed, the connecting references to other Web pages are also included when link analysis to determine ranking by such measures as popularity or importance of pages is to be performed.

Retrieval

The traditional retrieval process produces a ranking of all pages that contain one or more query words entered by the searcher which serves to restrict the number of pages examined. The retrieval operation consists of converting the query words to the same representation as the pages, calculating some similarity measure between the query and each page in the collection, and retrieving pages from the collection ranked in order of high to low similarity.

Boolean logic forms the basis of the conceptually simplest retrieval approach. Queries are formed as combinations of search words and logic operators such as AND, OR, and NOT; simple retrieval is implemented as set intersection, union and difference respectively between the query and pages. For example, the query "diet AND vegetarian" is implemented by retrieving pages that contain the intersection of "diet" and "vegetarian."

Though search engines generally compute a ranking derived from multiple factors such as links, the cosine similarity measure is a classical full-text retrieval approach that allows an intuitive graphical representation

used here for illustrative purposes. The similarity measure value is defined by the angle between the vectors representing words of the query and the words of individual pages. Determining the cosine similarity measure then requires representing the words of the query and pages as weighted vectors in a multidimensional word space where each axis corresponds to a different word drawn from the indexed pages.

Using the weighted vector space representation, documents similar to queries are located by finding document vectors in proximity to the query vector. A common similarity measure is the cosine of the angle between document and query vectors defined as

$$\text{Cosine}(D_i, Q_j) = \frac{\sum_{k=1}^t (D_{ik} \cdot Q_{jk})}{\sqrt{\sum_{k=1}^t (D_{ik})^2 \times \sum_{k=1}^t (Q_{jk})^2}}$$

in which D_i and Q_j represent a document and query vector respectively, D_{ik} and Q_{jk} are the weights of term k in the document and query, and t is the total number of terms. The range of similarity measures is then commonly normalized to a value between 0 and 1 to avoid word count bias.

Notice that if the query exactly matches all the words of a page, the angle between the query and the page vector is zero and the similarity measure is one; having few words in common produces a greater angle and smaller similarity. Figure 3 illustrates the indexing of page 1 containing the word “weight” and page 2 the words “diet” and “loss” where each axis corresponds to one of the three words. Representing the pages and query as vectors in three-dimensional space, the query vector for “diet” has a smaller angle with respect to the “diet” and “loss” text of page 2 than with respect to the “weight” text of page 1. Intuitively, the “diet” query is somewhat similar to the “diet” and “loss” page and not at all similar to the

Figure 3: Two pages indexed on the words “weight,” “loss,” and “diet” where page 1 contains the word “weight” and page 2 contains the words “loss” and “diet.” Similarity is measured as the cosine of the angle between a page and query vectors; the smaller angle corresponds to greater similarity. A query of “diet” would have some similarity to page 2 but no similarity to the “weight” page 1.

“weight” page. Based strictly on similarity to the query “diet,” the search engine would return a higher ranking for page 2 and a lower ranking for page 1.

One computational weakness of the vector space model just described is high dimensionality; each word effectively increases the dimension of the space. As noted earlier, the document space, consisting of those pages located by the spider, can be represented by a term-document matrix. For Internet-scale IR the matrix size becomes unreasonably large as does the dimensionality of the corresponding vector-space representation, that of the number of words in the document space. One approach that can significantly reduce dimensionality is latent semantic indexing (Deerwester et al. 1990), which is based upon the conceptually simple notion that pages having words in common are semantically similar. One distinguishing characteristic of this approach is that pages need not share a specific word to be semantically similar which allows the discovery and ranking of pages that do not contain the query terms. Though the implementation details are beyond the scope of this chapter, the fundamental insights are accessible and worthwhile. Key to this method is reducing the dimensionality of the document space by the process known as singular value decomposition, which, by ignoring very small components, creates an approximate model in a smaller dimensional space. By reducing dimensionality, pages initially represented by somewhat different vectors can now be mapped to the same vector. Ranking can be then be performed for queries using the vector space methods.

Search engines can exploit special features of pages to further improve retrieval quality beyond that possible using query and page words alone. Specific elements of a page, such as title words or anchor text, can be weighted to reflect a lesser or greater relative importance in ranking. When a page is retrieved, a Web search engine generally returns the calculated ranking, designated parts of the page such as the title and a description of the page content, some text surrounding the word found, and most importantly, the location of the page to retrieve.

Web search engines often follow an approach that utilizes the additional features of Web pages such as the *in* and *out* degree of hypertext links to improve the performance quality of IR. Page popularity and importance measures utilize the natural links between Web pages to refine rank calculated on word matches alone. Popularity can be defined to assign a higher rank to pages having more references from other pages, under the assumption that a frequently referenced page is more relevant than a page with fewer references. Figure 4 illustrates the popularity of page A to be greater than that of either B or C, as more links or references are to A than to either B or C.

Figure 4: The number of links to a page measures its popularity. Two links confer on page A the greatest popularity, B the next, and C the least popularity. The ranking based on popularity would be ABC.

Link or citation analysis is the basis of the PageRank algorithm (Brin and Page 1998), used by the search engine Google in prioritizing search results. Although a complete discussion of the PageRank algorithm is beyond the scope of this chapter, the basic concept is relatively straightforward. The PageRank of page A or $PR(A)$ can be calculated iteratively and is defined as:

$$PR(A) = (1 - d) + d(PR(T_1)/C(T_1)) + \dots + PR(T_n)/C(T_n)$$

in which:

$PR(A)$ is the PageRank of page A,

d is a damping factor that limits the contribution of linking pages and usually set to 0.85,

$T_1 \dots T_n$ are the pages that link to page A, and

$C(T_n)$ is the number of links from page T_n to page A.

Note that the term $PR(T_n)/C(T_n)$, the PageRank of page T_n divided the number of page links from page T_n , reduces the ranking contribution of page as the number of links on the page increases. This fits one's intuition that a page with links to many, possibly loosely related pages should not contribute as much rank as a page that links to only a few, likely more closely related pages.

In practice, the algorithm ranks a page higher than an otherwise identical one if a large enough set of pages link to that same page. This characteristic of the algorithm has proven sensitive to manipulation by a relatively few cooperating Web sites. Called "Google bombing," pages on multiple Web sites are constructed to hold essentially the same phrase and links to the target page. As more Web sites add the manipulation page, the rank of the target page increases to the point where a matching search query returns a high ranking of the target page. After a successful bombing, the algorithm ranks the targeted page higher than the referring pages that contain the actual query words. A manipulation page could consist of only the HTML page linking tag `bomb phrase`; after indexing enough sites containing the bomb page, Google will respond to the query "bomb phrase" by returning a highly ranked link to the target site `www.eatmorevegetables.com`. This particular manipulation method appears to have been first recognized by an individual (Mathes 2001) when searching for "internet rockstar" using Google.

A popular page as defined by the number of referring links is not automatically important. Importance of a page can be defined in terms of the number of links to the page and the importance of the linking sites. For example, a link from an Internal Revenue Service page to a page on taxes is intuitively more important and should confer greater rank than a link from a random individual to the same page. Authority ranking assumes that a page referring to another confers some measure of authority to the page. Authority and hub ranking utilize page links to identify authoritative pages on a subject and hub pages that link to many of these authoritative pages. The HITS (Hyper-text Induced Topic Selection) algorithm considers mutually referring pages to form authoritative groups on a subject (Kleinberg 1999), where the more links to a

Figure 5: Pages ABC and EF define two separate authority groups connected by hub page D to form a common subject authority

page from others within the authority group, the higher consequent rank of the page. Figure 5 illustrates a simplistic method of forming groups through mutual B and C links and common BC links to A. Page D marginally contributes to the authority of A but is not included in the ABC group as no other group member references D.

Hub pages are defined to have extensive links to authority pages and serve to bring together authorities on a common subject to form a mutually self-referential community. In Figure 5, page D acts as a hub that connects two separate groups into a single community. The resulting community is somewhat analogous to a single subject within a list service except that humans organize subject lists and the interconnecting links organize a subject community. Automatic grouping can produce more focused and higher quality references than strict similarity ranking but eschew the hierarchical organization that requires subject knowledge on the part of the searcher.

Which ranking approach produces the best result depends upon the user's search needs. Comprehensive search is the natural outcome of search based on word match ranking alone but yields no organization of the results. Existence and exploratory search can benefit from the reference-based ranking methods of popularity and importance. Popularity ranking anticipates that the information that many others reference represents common knowledge of a subject. Importance attempts to refine popularity ranking by organizing references into supporting groups. Grouping together documents that have common references will generally provide more homogeneous results and is best suited for exploratory search when some initial subject knowledge exists.

What Search Engines Search

Web pages can be richer sources of search information than traditional documents such as books and journals because of the natural connections formed to related pages and the characteristics of the hypertext markup language (HTML) used for writing Web pages. Web search engines seek to improve upon traditional retrieval systems by extracting added information from the title, description, and keyword HTML tags and by analyzing the connecting links to and from a page.

Recognizing the parts of a Web page that attract the attention of indexing spiders is critical to Web site designers attempting to raise the visibility of the Web site. Ideally, a Web site designer could give instructions to

visiting spiders on precisely how best to index the page to produce high-quality search results. Unfortunately, self-promoting Web sites generally have a history of hijacking spider indexing rules for their own benefit. In response to blatant self-promotion, few spiders observe a strict or stable protocol as to which page to index or which parts of the page are considered important. However, most spiders do observe the following common guidelines (Sonnenreich and Macinta 1998).

Content

The result of search is the page content that the searcher sees and reads. The readable text, as displayed by a browser in Figure 6, provides the bulk of the words indexed by the spider.

Characteristically, less common words increase the page rank but are valuable only if a searcher uses that word in a query. Using many different words in a page improves search breadth but the words must be obvious for a searcher to use in a query. Including important keywords in the title, increasing the frequency of a keyword in the text and placing keywords near the beginning of the page content can improve page rank on most search engines. Be aware that repeating a keyword multiple times in the title may gain a higher ranking but many search engines ban blatantly bogus attempts at manipulation and may reject the page or site entirely. The challenge to the page writer is to find the right keywords rare enough to stand out, descriptive of the content subject and that are familiar to the searcher. Bear in mind that indexing spiders may examine only the first few hundred

words of content so it is important to provide descriptive keywords early in the content text.

Tags

HTML tags are not generally visible to the reader but do contain information important to the spider. Along with content keywords, spiders also extract the page location and may examine HTML tags when indexing a page. The Web site designer can influence the page rank and provide more descriptive results to the searcher through the tags. Figure 7 gives the source for the HTML page rendered in Figure 6 to illustrate the page content and use of the following tags.

Keyword: The HTML keyword meta-tag contains human-defined keywords to augment the automated indexing of the page content. One use of the tag is to provide alternative words or phrases for those in the content, for example, using “PDA” in the content and “personal digital assistant” as keywords. Unfortunately, promoters have so often abused the keyword tag that many spiders generally ignore it. When search is limited to a trustworthy site, such as a university Web site, keywords can be valuable to the designer and searcher.

Description: The description meta-tag provides a short content summary for display when the search engine retrieves the page. Figure 8 illustrates how a search engine would display the description tag with other page information.

Title: Indexing the title tag independently allows explicit searches on the title; the search engine can also display

Automated Search Engines

Automated Web search engines have two main tasks; one of indexing the Web information, the second of answering search queries from the index. First, an indexing program visits a Web site much as you would with a browser, normally starting at the default homepage, visiting connected pages and indexing the site information ([see Figure 6](#)).

Figure 6: How the HTML of Figure 7 would appear in a browser

How Search Engines Work

Human lists and automated search engines.

<http://www.insearchof.org/how.htm>

Figure 8: An example of how a search engine might respond to a query of “search engines.” The word “indexing” is part of the keyword meta-tag and embedded in the text content. The title is “How Search Engines Work” and the description meta-tag is “Human lists and automated search engines.” The document URL “www.insearchof.org/how.htm” and the title provide links to the complete document

the title as part of the page information, as in Figure 8. As previously mentioned, keywords placed in the title may also improve page rank.

Heading: The large print of headings catches the attention of the reader and also is important to an indexing spider. The influence of headings on rank generally follows the scale of the heading number, so that weight of the words of a level 1 heading is greater than the weight of the words of a level 2 heading.

Links: The spider follows link connections to other documents through the attribute and hypertext reference tag; for example, “``” directs the spider to follow the link to the index page “Figure6.html.” The popularity and importance methods would generally rank a page with many links from other pages relatively high. Influencing other sites to link to a site’s pages is not easy, generally depending upon good content to attract recognition. However, cross-listing agreements to share mutual links with other sites are a technique that can provide a quicker start to that recognition. Link farms are commercial services to increase link-based rankings by creating artificial links to subscriber sites; however, search engine sites generally consider artificial manipulations to be adversarial and can remove offending sites from the search engine index.

Anchor: The text associated with an anchor can be used to describe the page that the link references. For example, “`Human lists and automated search engines.`” defines hypertext describing the contents of the page defined by the link address. The Google search engine considers anchor text of special importance (Brin and Page 1998) in providing an accurate description of the linked page and text for indexing of pages that have not been spidered.

What Search Engines Ignore

Can designers accidentally make their Web sites invisible to spiders? Are all spiders the same? Most spiders purposely ignore or cannot see large parts of a page that human readers might see and manipulate; certain page elements can hinder or prevent indexing. The most common spider problems and solutions are the following:

Frames: The purpose of frames is to visibly divide a browser screen into several parts, but unfortunately frames can stop an indexing spider and create confusion for visitors arriving from a search engine. At least three separate pages are needed for frames: a hidden frameset

page that defines the frames and links visible pages into the frames, a second page for visible content, and a third that is often for navigation. A spider normally arrives at the hidden frameset page but must understand how to handle frames in order to follow links to the other, visible pages. Spiders that do not understand frames simply stop and never index further. For those spiders and browsers that do not understand frames, the remaining site pages may be unreachable. Because frames cause some spiders problems, the obvious solution is to avoid the use of frames entirely. However, when the Web site designer is forced to use frames, including the “noframes” tag exposes alternative text for navigation and content to frame-ignorant spiders and browsers. The “noframes” tag designates text to be displayed in place of the framed pages, effectively duplicating the page content and design effort. Spiders that understand frames create a different problem. Visitors can now arrive at a content page directly from the search engine rather than through the main frameset page as the Web site designer intended. Without the main frameset page there is no navigation page either; visitors can become wedged on a dead-end page and, without any navigation, forced to leave the site. One solution is to place a link to the main frameset or site home page in every navigation and content page to help keep the visitor on the site. Of course, another solution is to avoid frames altogether.

Scripts: Most spiders ignore script programs written in JavaScript or other scripting languages; others simply index the script program text. Spiders that index the script may also index only the first few hundred words of the document and possibly never reach the content. Place important content and keywords before scripts and, for pages that are mostly scripts, include title, keyword, and description tags.

Java Applets and Plug-Ins: To a spider, a Java applet, plug-in, or other browser-executed program is invisible. For indexing purposes, include descriptive content and tags within the page that contains the program reference.

Server-Generated Pages: Spiders may ignore any unusual link references, such as ones that do not end in “HTM” or “HTML.” For example, a spider will follow the connecting link “``” but may not follow the link to the Web server program of “``” as a result of the ending “ASP.” Generating the Web site main page with a server program could mean that some spiders ignore the complete site. One solution is to provide some HTML pages for the spider to index and navigation to guide the searcher to generated pages.

Forms: Collecting visitor information is one of the most important functions of many Web sites, but spiders do not know how to fill out forms; a site login form automatically stops a spider. Spiders that do index the content and links of the page containing the form create potential problems by leading visitors directly to the form page from a search engine rather than through pages intended to precede the form. An example would be an airline reservation system with forms for itinerary and payment. Visitors arriving directly at the payment form would obviously have problems; consider adding links back to a starting page.

Robot Exclusion: Forms represent one good reason to exclude spiders from indexing certain pages. Two standards exist that instruct well-behaved spiders on excluding specified pages. The recognized standard (Koster 1995) is the “robots.txt” file that lists a site’s acceptable and unacceptable directories, pages, and robots (i.e., spiders). A single robot.txt file exists for the entire Web site, which only the site administrator can access, creating a maintenance bottleneck as multiple designers make changes to the site. A better but less accepted solution defines a special “robots” meta-tag to specify how to index each individual page. Options are that every spider or no spider should index the page, the page should be indexed or not, and the page links should be followed or not.

Images: Spiders may index the image location, image title, and alternate text but that is probably all. For searchers to find the image, include some additional information about the image in the page content and the HTML tags.

Deeply Linked Pages: Most spiders completely index only small sites, generally indexing only limited pages on each site. Spiders limit indexing to several connecting links deep, ignoring pages linked beyond that depth. As a rule, keep pages important in attracting visitors linked directly from the site home page.

Reorganization and Broken Links: Resist the urge to reorganize the site. Until all the spiders come again, the new greeting for visitors arriving from search engines to pages that have been renamed or otherwise permanently hidden may be “404 Not Found.” Adding new pages to the site is fine; just leave existing page locations and names alone.

File encodings: Although many search engines translate certain specialized file encodings such as PowerPoint or PDF (Portable Document Format) to text for indexing, any file type that cannot be translated will be ignored. One simple solution is to provide a descriptive page for the spider to index with links to the encoded file.

Metasearch

As a result of different search algorithms, sites indexed and the type of search required, one search engine can never perform the best in all cases. Individual search engines produce results biased in ways that are unpredictable and often invisible to a searcher. Sending the same query to several search engines will obtain widely different results. One study on search engine bias (Mowshowitz and Kawaguchi 2002) demonstrated that querying nine popular search engines for information on “home refrigerators” produced 14 different brand names in the cumulative top 50 results of each engine. Reporting of the brands was unpredictable and uneven across search engines consulted; several brands were found by only a single search engine and no search engine found a majority of the 14 brands. And obviously there was no clue at all as to the brands not found.

Given that individual search engines index only a small fraction of the Web and the degree of index overlap among a group of search engines may be small, it makes sense to consult multiple search engines. Consulting several engines is intuitively appealing and nearly always improves recall. Using multiple search engines for a

single search is one strategy for improving the likelihood of finding relevant information. Metasearch engines automate multiple searches by sending the query to several standard search engines and organizing the fusion of the results uniformly. Although increasing the number of information sources will generally improve recall, it is also likely that precision will suffer correspondingly. Balancing these conflicting goals is the key challenge in designing a metasearch engine.

The essential architecture of a metasearch engine (Dreilinger and Howe 1997) consists of a dispatch mechanism to determine which search engines receive a specific query; interface agents to contact and adapt the query and result formats of each search engine; and a display mechanism that creates and displays a uniform ranking of results after removing duplicates. By depending upon the direct results returned from regular search engines, metasearch engines cannot expand or improve upon the information sources. However, to a searcher, metasearch represents an obvious improvement over a single search engine by the simple increase in the number of search engines consulted and the corresponding increase in the fraction of the Web examined. Metasearch is also a commonly integrated into the text-mining applications discussed later.

Web Site Issues

Web site success requires the intersection of the goals of users and owners which have lead some researchers (Belanger et al. 2006) to develop site goal taxonomies to better measure when the site matches its planned purpose. One obvious site goal is to attract visitors and they most often find a new site via a search engine implying that building an easily found and searched Web site is critical. A study of search success (Spool 2001) illustrates the challenges of designing a Web site for search. After watching 30 searchers search different sites for content that was on the sites, the study concluded: “The more times the users searched, the less likely they were to find what they wanted.” Single searches found the content 55 percent of the time, those searching twice found the content only 38 percent of the time, and those searching more than twice never found the content. Nearly 23 percent of the searchers received a “no results” response on their first searches, causing most to give up immediately. For those who continued to search, results only grew worse. Further compounding search problems is the prevalence of invalid links to pages that are no longer accessible; one study (Lawrence et al. 2000) gives the percentage of invalid links ranging from 23 percent of 1999 pages to 53 percent of 1993 pages. Although the study did not define the human or IR system problems with search, the collective message seems clear: design the site and pages for search and test that search works.

Web Site Discovery

How is a Web site discovered by a search engine? Given that any one search engine indexes only a small fraction of the Web (Lawrence and Giles 1999) and that fraction is declining, the answer is of critical importance to the Web site designer hoping to attract visitors. Most search

engines accept free submissions for indexing all or part of the Web site and paid submission to multiple search engines is available through service companies. Links from other sites will also widen visibility and speed the discovery of a Web site; sites with few links have a lower probability of being indexed. The spiders of some search engines also identify new sites automatically using registered domain names as a starting point. The most certain and direct approach is to purchase keywords on a search engine; a query with a site's keyword is guaranteed to return the site, normally before those listed by the merit of rank. Once a Web site is discovered by search engines, the methods examined earlier to influence automated search become important, though often the best strategy is to develop and maintain high-quality content to attract and cultivate loyal visitors who link to your site. Where content quality or time is in shorter supply than money, the paid listing will guarantee that a site is highly ranked by at least the paid promotion search engine.

Measuring Search Success

How can a site's owner determine if efforts to attract search engine attention have been a success? Search engines represent the most obvious and direct means to check if and to what extent a specific search engine has indexed a site. Search engines generally provide searcher controls to limit search to a specific Web site; these same controls can also provide feedback to point out search problems with the Web site. Although tests with individual search engines will determine if and how a Web site has been indexed, it will not tell if, why, or how anyone visits. The site server holds the primary information on Web site success in the server access log file. The log holds details about every attempted or successful visit; Table 1 lists the information retained in the Web server access log following the Common Logfile Format. Free and commercial analysis software can produce detailed summaries and graphs of the log; however, the most telling information about search success is contained in the following three fields:

Client Request Line: Contains the page on the server the visitor requested. For visitors arriving from a search

engine, this contains the link to the page indexed by the spider.

Server Status Code: Status codes starting with a 2 or 3 indicate success (3 indicates a redirect); those starting with 4 or 5 indicate an error (4 a client error, 5 a server error). In Table 1, the "mainpage.htm" page does not exist, earning the visitor a "404 Not Found" response from the Web site.

Referring Site: The visitor client reports the referring site address. In Table 1, the visitor arrived via a reference to "mainpage.htm" made by the hypothetical "www.insearchhof.com" search engine.

Of what value is the access log? Examining the log entries can point out search errors and successes. Counting the number of visitor requests (i.e., client request line) to each page immediately grades pages on success in attracting visitors and, by their absence, identifies those pages that failed. Investigating the referrer list will show how visitors arrive at a Web site; search engines missing from the list have not indexed the Web site or rank its pages below others. A table of visitor page requests with the referring site will clearly show which search engines successfully found specific pages and can flag pages that create indexing problems for particular search engines. As discussed earlier, some spiders are stopped by frames, only index the first few content lines, or crawl a limited number of links on each site. Pages that are never accessed can indicate indexing problems for the spider or navigation problems for the visitor. Examining the access log file is a good starting point for finding these and other potential search engine and link problems.

Can the log tell us when a complete site or some part of the site is broken? Interpreting the three fields for client request line, server status code, and referring site from the Table 1 example tell us that the "www.insearchhof.com" search engine referred a visitor via an indexed page link to "mainpage.htm" and that link is now broken, as reported by a "404 Not Found" message. A likely reason the link broke is the Web site was reorganized since the last visit by the "www.insearchhof.com" spider or the page location on the site otherwise changed. Should we inform "www.insearchhof.com" they now have a problem

Table 1: Server access log fields in Common Logfile Format

Access Log Field	Example
Client IP address	24.10.2.3
Client identity – unreliable	–
Authenticated client userid	–
Time request completed	[01/may/2006:17:57:03 –0400]
Client request line	"GET/mainpage.htm HTTP/1.1"
Server status code	404
Referring site	"http://www.insearchhof.com/search.html"
client browser	"Mozilla/4.08 [en] (WinNT; I;Nav)"

and need to fix their link to point to the new page location? Un-reorganizing an active Web site is no solution because other search engines may have already indexed the new site organization. A limited solution is to redirect visitors requesting each old page to the new page location through the server configuration or an individual page redirection file for each page moved.

TEXT-MINING

Humans are masters of pattern recognition and the advantageous association of seemingly unrelated facts, no doubt an acquired survival skill. Although Internet text IR as characterized by search engines has proven valuable in directly locating sources of information about which one has some knowledge, queries often return thousands of potentially relevant documents, more than can be effectively managed. By design, the relationship on which search engine retrieval algorithms determine commonality among documents is that queries and text share common words rather than necessarily sharing common concepts. Text-mining represents a natural extension of text IR to extract higher-level information from unstructured data, often to determine underlying structure and relationships among a collection of information where none is apparent, serving to organize information into recognizable patterns. Text-mining of unstructured information shares comparable goals to that of data-mining applied to structured databases. The notion of information mining implies revealing information that is buried within non-obvious patterns requiring deeper analysis than commonly provided through search engine queries. Some common examples of text-mining include analysis of writing styles to establish authorship and the U.S. government's purported ECHELON intelligence gathering system. An early text-mining example (Swanson 1989) sought to establish an unpredicted connection between a disease (Raynaud's disease) with possible cures (fish oil) through a trial-and-error strategy connecting existing research literature on the disease and unrelated studies that might produce a cure. Clinical tests later demonstrated the validity of the disease and cure link.

Ideally, text-mining could be as simple as text searches and results measurably related to query requests. But where search has the one clear function of matching search queries with documents and measurable results (e.g., precision) text-mining, by attempting to extract information that may only be apparent through interconnected evidence, is at present complicated by the need for multiple approaches with a large degree of subjectivity as to performance results. Text-mining technologies (Fan et al. 2006) are based on elements of natural language processing, needed to analyze text and extract relevant features such as proper names and parts of speech. Individually, key technologies applicable to text-mining include information extraction, topic tracking, summarization, categorization, clustering, concept linkage, information visualization, and question answering. In each, the overriding goal is to automate some human approach to understanding unstructured text but at the speed and accuracy of a machine. Few are general or scalable enough to directly mine the text of the

Internet but are useful tools for restricted domains such as a financial news feed. Finally, text-mining is still an area of very active research; production systems and support by major data mining vendors such as SPSS and SAS exist but few mature technologies are generally available. The following presents explanations of these technologies and some example systems.

Information extraction (IE) is generally a more sophisticated analysis than the word matching IR as supported by search engines. IE is able to recognize word usage in the context of other text but does not fully achieve text understanding. Further, separate documents are generally considered independent, meaning no attempt is made to relate elements of one document with another. The goal is to extract structured information from a targeted domain, such as building indexes of new product type and company name from financial news articles for subsequent use in structured IR databases. As with full-text IR, IE performs word stemming, thesaurus lookup and other operations but must also understand, from the earlier example, how to recognize a company and a new product. There are two basic approaches (Appelt and Israel 1999) in constructing an IE tool, either automatically by analyzing, perhaps statistically, a corpus of training examples or hand-engineering the grammars necessary for extraction in a particular application domain. In either case, the resulting IE tool operates in the restricted domain.

Topic tracking attempts to categorize new documents by detecting a shared feature with those of a training set, potentially predicting new documents of interest based on specified preferences or previous documents viewed and added to a profile of user preferences. Yahoo! (www.alerts.yahoo.com) and Google (www.google.com/alerts) offer limited topic-tracking services for Internet sources including news and Web pages. Services range from airfare price alerts to notification when a specified Web page becomes highly ranked. These services are essentially applications of text IR technology, for example, simply matching text to identify topics. The difficulty in a text matching approach is that different topics often use the same text and the same topic may use different text which produces no matches. In contrast, TopCat (Clifton et al. 2004) was designed to organize news geographically whether or not the geographic area was mentioned. The approach attempts to identify key language concepts such as people, places and organizations to determine those that tend to appear together for grouping as topics.

Summarization, such as that provided by Microsoft Word's AutoSummary tool, attempts to reduce a document to a few representative sentences. Strategies include statistically weighting document sentences based on word frequency to calculate the average relevance of each sentence (Neto et al. 2000) and heuristics that give higher weight to sentences based on location, such as the one following the introduction section. Summarization can be combined with other technologies such as topic-tracking and clustering to summarize all suggested or clustered documents to a single representative phrase.

Clustering technology groups those documents together that share a common topic. Each cluster of documents is characterized by keywords extracted from those

Figure 9: Clusters and number of members in each produced by the query “information retrieval”

documents allowing individual documents to be a member of multiple clusters. Rather than placing documents in predefined, static topic groups as in categorization, the clusters are constructed dynamically from a given document training set. Clustering would naturally group documents by language and disambiguate queries containing multiple use terms such as acronyms. A Web clustering application (www.clusty.com) powered by the Vivísimo Clustering Engine (Vivísimo 2006) retrieves documents by a normal query to multiple search engines and attempts to organize those documents into related clusters labeled by the dominant topic. Please refer to Figure 9 for an example of the clustering results; also produced by the query but not shown are the standard search engine individual page rankings.

Categorization generally implies placing documents into predefined groups, somewhat similar to clustering but the groups are static and the domain is restricted. Cookbooks are an example, often organized by grouping key ingredients in which dishes containing chicken are rarely categorized with desserts but may show up in other categories. Weaknesses of clustering addressed by categorization include the difficulty in accurately labeling groups automatically. Clustering must determine representative text to describe the group or list keywords used to form the group; categorization groups and labels are, of course, human defined. Categorization is obviously limited to restricted, predetermined domains.

Current search engine IR technology lacks the ability to organize any but superficial text patterns and the implied relationship defined by hyperlinks. Text-mining attempts to bring structure to unstructured text by understanding, at least parts, of the patterns in text. Mechanically finding and exploiting patterns as part of IR complements inherent human pattern matching skills; accurately and efficiently performed, large collections can be organized for effective information retrieval. Unfortunately, most current text-mining technology achieves neither the accuracy nor efficiency necessary for Internet-scale IR. Alternatives generally include elements of manual classification schemes in which human intelligence serves to define information features (e.g., subject, date, location) and annotate as metadata; essentially imposing a structure rather than discovering one. MPEG-7 and the Semantic Web, discussed later, are examples that utilize some elements of this approach.

EXPLORATORY SEARCH

Exploratory search can be an alternative to or complement a purely analytical strategy for exploring information. Exploratory search seeks to create an interactive IR system by placing the searcher more in control of the direction and pace of search, providing organization, cues, or other guidance to create an uninterrupted exploration with strong human participation. Hypertext browsing was recognized as a non-analytical search strategy (Marchionini and Shneiderman 1988) before the invention of the Web, an exploratory strategy invited by navigating the links connecting one document to another. Though browsing is not directly supported by the most common Web search engines, it is often performed ad hoc by the searcher seeking to locate further information by following navigation links from the ranked result list and those embedded within a retrieved page. The following will examine some of the variety of exploratory search methods that have been developed; many that visually illustrate information relationships in spatial dimensions and many that include elements of text mining to reveal those relationships.

As noted, search can be divided into the two broad types of analytical and exploratory (Marchionini 2006). Analytical search depends upon prior knowledge and is appropriate for retrieving facts, known-item search and existence verification. The search engine effectively supports analytical searches in which existing knowledge of the information sought is used in formulating a query and recognizing the relevancy of the results. Early IR researchers (van Rijsbergen, 1979) recognized that information discovery is an iterative process requiring different search strategies that produce repeated strategy transitions in between. Exploratory search is needed for learning or investigation of new information and is appropriate for knowledge acquisition, comparison, analysis, evaluation and discovery; tasks requiring a user interface that complements IR by adapting to the changing needs of the searcher as the search for information evolves. The ideal user interface combines multiple search strategies in a way that transitions occur smoothly and naturally to support the discovery process; this has led the IR community mindful of human limitations and strengths to incorporate human-computer interfacing developments to involve humans more actively in the search process.

An idea common in many exploratory search interfaces is the notion of browsing as a means to rapidly navigate and explore information and some form of feedback to focus further exploration. Browsing can exploit existing connections and those relationships determined between information sources based on methods such as those described in text-mining. Feedback describes the mechanism by which a system can improve future performance by taking into account results from past performance. In analytical search, the searcher considers the results (feedback from the search engine) of one query to modify the next; the search engine eschews feedback by considering each query as independent of others. Exploratory search uses feedback from the searcher and IR system. Search feedback can be obtained directly from the searcher, by requiring ranking of results positively or negatively for

Figure 10: The graphical relationships and categories presented for further exploration by the WebBrain query of “information visualization”

use in the next retrieval round, or indirectly by presenting multiple navigation choices to explore further.

Browsing is intended to be rapid, requiring obvious, condensed choices for effective exploratory search. CiteSeer (citeseer.ist.psu.edu) promotes browsing of computer and information science research literature through concise textual cues to a paper's significance by ranking on the number of citations, indexed date, citations weighted by year indexed, et cetera and providing direct access to other publications associated through citation linkage for exploring further related research. A typical session begins with a subject related text query to generate a ranked list of documents; selecting one produces several navigation categories for browsing (i.e., bibliography, citations, similar documents based on text, and other documents located on same site) inviting exploratory search through several different information criteria groupings.

Discovering information seldom occurs along a predictable path or using a single strategy. Exploration is often over several dimensions whose importance changes as the user's investigation and knowledge of the domain evolves. Given the variety of dimensions on which to organize information, for music—by composer, genre, period, and so on, and the appropriateness of different search models at different points in the information discovery process, a Swiss-army knife approach to discovery tools is often necessary though integration difficult. One such example is mSpace (www.mSpace.fm) (Schraefel et al. 2006) which provides keyword search, dimensional views (e.g., music grouped by era), and audio clips. The user is able to dynamically control exploratory focus and direction by selecting items within a dimensional listing or by rearranging the hierarchy of the dimensions to change the exploration viewpoint. This is somewhat similar to sorting on the instances in multiple categories but changing the category hierarchy or the categories explored to achieve a different organization or view of the instance information. In this example, categories not only serve to organize related instance information, but also provide cues for further exploration; hovering over a category produces an exemplar of that grouping that may be based on expert recommendation, collaborative filtering or, surprisingly effective, random selection.

Visual text-mining (or information visualization) graphically presents relationships between documents to allow users to quickly comprehend and navigate the information groupings; a narrow definition of text-mining that focuses only on reasoning about document organization. Internet-scale implementations include Web-based WebBrain (www.webbrain.com); a metasearch engine that extracts topic clusters from metasearch results (K-Praxis 2003) and presents the relationship visually. WebBrain labels topic clusters by keywords extracted from

the search results, supporting exploratory browsing by issuing new metasearch queries when the topic label is selected and reclustering the new results. An initial query on “information visualization,” as illustrated in Figure 10, produces topics with labels that include “Databases>Data Mining” with “Text Mining” as a subtopic of “Knowledge Discovery.” Browsing over the “Text Mining” label visually highlights the relationship connection to “Knowledge Discovery” and “Databases>Data Mining.” Selection of the “Text Mining” category results in a new metasearch on text-mining and categorization, continuing the exploration process. Note that analytical search is also supported, though not shown in Figure 10, through an aggregated list of the metasearch ranking results.

Another Web-based example is the metasearch, information visualization engine, KartOO (www.kartoo.com). Information navigation is through a dynamically categorized topic list labeled by keyword and a graphical mapping of the information sources (i.e., Web site); the map includes spatial cues of category to site relation in the form proximity and quantity by font size; visual connections are drawn between topics to sites. Figure 11 illustrates how major category topics are overlaid within map contours to illustrate strength and proximity of topic relationship. Passing the mouse over a Web site displays topic links and a synopsis the site contents.

Basic elements of exploratory search are transitioning from research topics to standardized software components. Software vendors (Inxight, www.inxight.com) now provide development tools to implement user interfaces for navigating information sources available on an individual Web site, for example. A graphical interface displays hierarchical relationships between information groups in a connected format that allows the user to incrementally follow links from a parent to a child or skip over several generations at a time (Inxight 2006). Multiple parent and non-hierarchical cross links provide the ability to redirect focus in the direction determined by the user. Using such an interface, a Web site hosting a large bidding auction could then display the site auction items as a hierarchy graph showing “computers” as the parent of “hardware” and “software.” Visual cues of link size and color can indicate the comparative strength of a relationship allowing the searcher to quickly assess the information direction to explore further.

MULTIMEDIA INFORMATION RETRIEVAL

Text-based IR as characterized by search engines certainly dominates Internet IR by almost any measure whether financial, by popularity, scale, or by technological maturity.

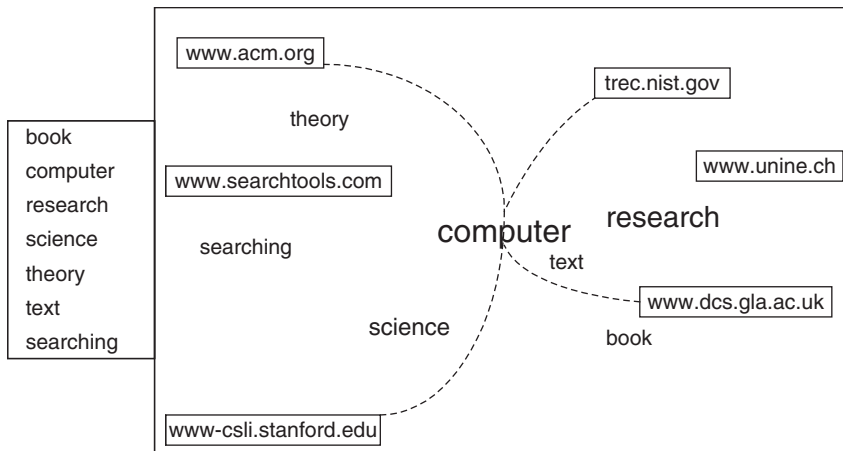

Figure 11: Information visualization of KartOO graphically displays an information map of Web sites in proximity to the related information category. Selecting a category dynamically connects all related sites; “computer” is connected to four related sites

Efficient algorithms for text indexing and retrieval provide a key advantage to search engines. However, the technology is limited to direct search only on text and not other media accessible on the Internet. As noted earlier, an understanding of text-based IR by search engines is a useful foundation for understanding other IR approaches and media. We will now see that search engines are in fact often directly incorporated with other schemes and that text is often used for IR on other media.

Visual

Visual information presents many challenges to IR. Where text exists in a domain formally defined by the language characters, common spellings and vocabulary, visuals have few formal constraints and far more variables, such as colors, texture, and motion. Visuals can be static as in photographs, cartoons and data graphs or temporally and spatially changing as in a movie. Visual information exists in many forms: as figures surrounded by related text, annotated pictures (static images) and video with audio, to name just a few of the many available on the Internet. Not surprisingly, a wide variety of IR methods have been developed to exploit one or more multimedia features.

Before examining visual IR in detail, we should first consider some of the key issues. Although methods of searching vary, the ultimate goal is generally to retrieve a relevant visual from among many available. In a text search, the query is submitted and a set of pages containing those words is returned; the query is essentially an example of text to be matched. The text query “flying horses” should produce a set of relevant pages that include the mythical Pegasus. A visual search can also use text queries that describe the visual sought, for example, the same text query “flying horses” should produce a set of relevant images that include Pegasus. Matching query words to visuals, however, requires a degree of understanding of the visual content. A visual search can also use examples of the visual sought as a query, an image of Pegasus should produce a set of relevant images that include other images of Pegasus. A purely visual search has many more possible dimensions for matching than does text, such as color and texture, providing distinct

opportunities and challenges compared to text IR. Fundamental questions about visual search include: “how are queries expressed in a way that the user can understand and provides sufficient precision to produce relevant results?”, “what component of a visual serves as an example for search?”, and “are results understandable in a way that allows further queries to be refined?” The following section will provide an overview of the predominant general approaches with illustrative examples from specific cases.

Text to Retrieve Visuals

Librarians retrieve images by first annotating with keywords and possibly other metadata and subsequently retrieving images by the corresponding annotations. A similar, automated approach to retrieving visual information transforms the problem to one suited to existing text search engine technology. Since many visuals have some associated text such as the captions of Web page images and nearby surrounding text, the most simple of approaches assumes that any text near the visual describes the visual. This adjacent text-to-image association is used by a number of commercial image search engines such as Google (<http://images.google.com/>). Visual queries are then the same as text queries using essentially the same search engine technology. Although a close text-to-image association is an appropriate assumption in some domains such as captioned news photographs or figures in journals, such an assumption is not necessarily valid for all Internet visual IR. Obviously, this approach works only as well as the degree of implicit association of the text to the visual, producing satisfactory results for restricted visual collections such as art museums where the visual is professionally annotated with text.

Visual IR based on text searches require that either annotation exists or the annotation process be automated. One illustrative example that based retrieval on both existing text and visual features is *WebSeer* (Swain, Frankel, and Vassilis 1996) an image retrieval system utilizing surrounding HTML text and the classification of the image to restrict the search to a subset of images. The classification is based in part on known differences between photographs and drawings such as number of colors and the

degree of color saturation. Further classifications could restrict the search to photographs with faces or cartoon drawings for example. Text queries could then be combined with visual classification information on whether the image sought was a drawing or photograph.

Text annotations can be generated directly from the visual itself in several ways. Visual features (such as predominant colors, texture, and shapes) can generally be determined from a still image; motion images (video) can be analyzed similarly while possessing other dimensions (time and motion) in combination with other media such as audio. The difficulty is capturing the semantic information of the visual for conversion to text. Image-to-word transformations often use some form of a learning algorithm (Mori et al. 1999). Hand annotated images generally serve as training examples from which categories of images and associated index words are formed. New images are then collected, analyzed and assigned one or more of the textually labeled categories determined from the training set. A text query would then return images with matching labels. However, a single label to describe an image forms too broad of categories to be useful. To improve precision, image-to-text systems commonly subdivide the image into regions and assign each region a label so that one image could have multiple labels for different regions; the image would then appear much as a text document to a search engine. Associating a characteristic region and label is a key problem. A somewhat intuitive approach (Pan et al. 2004) uses blob regions or parts of the image a human would generally describe as a distinct region such as sky, grass or an automobile; training data consists of images with blob regions and corresponding words. Blobs are represented by a vector of features including color, position, shape, and texture; when matched with blobs of new images, the new image is assigned the blob labels which can be indexed for image retrieval. Once again, the key idea is to transform the image into associated text that can then be used for indexing and retrieval.

Content-based video indexing and retrieval methods similarly attempt to create a text index of a video for text IR (Sebe, Lew, and Smeudlers 2003). In addition to visual information (e.g., color), video may contain captioning text, characteristic audio (such as a national anthem) and speech that can be extracted and converted to text for indexing. For example, speech can be directly converted into text and combined with associated segments through image analysis to construct an index to specific segments of a video. The image analysis consists of video segmentation, in major part detecting shot boundaries to segment the sequence of video frames into similar visual elements such as those contained in a movie scene; text from speech and other extracted scene components can then be associated temporally with the video segment and indexed for later retrieval.

Text searches against assigned annotations in media such as images remain the most successful approach to image retrieval. Text contains higher-level semantic information than features such as color or texture. But professional hand-labeling is in general prohibitively expensive and, except for iconic cases such as an image of the Statue of Liberty, often cannot be definitively classified for later retrieval by non-experts. Crowd-based

approaches or *folksonomies* (Lew, Sebe, and Jain 2006) is an attempt to harness the collective wisdom of the crowd in assigning annotations. For example, multiple individuals may assign different annotations to the same image; each unique annotation provides a potentially different categorization while duplicates can reinforce or strengthen a categorization. Flickr.com and Del.icio.us are example sites that use the general notion of the collective crowd wisdom on the Web for creating text annotations of their media.

Static Visuals Without Text

Users generally want to retrieve photos by semantically describing objects in the image at a high-level, such as *bridge* or *train*, rather than by low-level image features, such as a color, texture or geometric constructs. A purely manual approach to visual retrieval might start with a mental query as in “find photographs of the Brooklyn Bridge.” An individual, assuming they have seen the Brooklyn Bridge, transforms the query into retrieval by recalling the image and proceeding to match the mental image with photographs, possibly retrieving some other bridge pictures similar in appearance. For an automated system using text as queries for visual IR, either the retrieval system must conjure an image from the text and then match similar images or, standing the problem on its head, the system must extract semantic meaning as text from the visual collection and retrieve visuals based on the text (as described in the previous section). Either approach, for an unrestricted domain image collection is daunting.

Systems that retrieve visuals based on visual features alone must first be presented a query; the form may be words or an example visual. Word queries describing a visual by feature components such as color or texture (patterns) can produce high recall but generally low precision results. For example, the texture query of “red checkerboard” should retrieve visuals of a red checkerboard. Indexing visuals on predominant colors is straightforward but retrieving predominantly red visuals from the Internet would not be useful (however, for some applications, finding images with the predominant color of flesh may be). Querying in additional dimensions, such as texture, to improve precision results in explosive indexing growth and complicates the query interface with a shopping list of features; perhaps more importantly, users have difficulty associating image features presented by the user interface with an unseen, imaginary image. The difficulty in describing image components to produce high precision retrieval has effectively limited this approach to restricted domain, non-Internet image collections. One noteworthy example is the Query By Image Content (QBIC) system of IBM that powers image retrieval of the artwork presented at the Hermitage Art Museum in St. Petersburg, Russia (www.hermitagemuseum.org/fcgi-bin/db2www/qbicSearch.mac/qbic?selLang=English). Queries can be defined by selecting colors from a two dimensional chart and choosing a category such as painting or sculpture. Images of the original art matching the color and category are retrieved from the collection for viewing.

Visual examples used directly as a query offer an alternative to a text or image feature query. One approach is to present an example image as a query, somewhat as in the

query by example (QBE) used in text searches, and search for images with similar features such as color and texture. After retrieval, the user can refine further queries by feedback that selects positive or negative examples that move closer to the desired image. This, however, leads to the *zero image* problem, how to generate the first image as the query. Solutions range from an initial text query to retrieve a first set of exemplar images, browsing an existing image catalog, to submitting the URL to a known example image.

In some cases, visual IR demands specific example images as queries. For applications where visual identification is the primary purpose, such as optical character recognition, trademark, or face identification, some initial training examples must be available along with the images that serve as queries. The queries, when correctly identified, can also provide feedback as additional training data. An Internet company, Riya (<http://www.riya.com>), exploits this approach. Given a set of training photos explicitly identifying individuals by name, Riya retrieves the names of those individuals from new photos. The new photos, when correctly identified, then serve as additional training data. As of this writing, Riya's search space is limited to those photos submitted directly to the site so is relatively small; plans have been announced to extend photo identification of individuals to the Web.

Text search engines are successful in part due to the relatively free and open-ended character of queries formulated by the user; the user can create the query without the need to locate an external source of a similar query. Although text queries possess aspects of QBE in that those documents with text matching the query will be retrieved, creating the query is relatively easy and retrieval feedback generally useful for refining the query. Creating an analogous image query would be challenging for most users so different approaches are required.

One weakness with a pure QBE approach is that user input and control is limited to existing examples. Providing users greater control to query representation was exemplified by *Blobworld* (Carson et al. 1999), which operated under the basic principle that users search for objects such as boats or bridges rather than features such as color or texture. Blobs generally correspond to an object that can be defined as a somewhat homogeneous region in terms of components such as color and texture; these components then serve as indexes, and new images can be added to the collection by automatically dividing the image into recognizable blob regions. Unlike most text search systems, the user interface is an important element of the search process. Queries begin with an example image, which is returned with objects automatically identified marked as blobs from which the user can select objects (blobs) to match. The process is then repeated as the user selects blobs from returned images to submit as refined queries.

Motion Visuals

Motion visuals, generally characterized simply as video, present a large, multidimensional information source for retrieval. Motion alone adds temporal and spatial dimensions to visual information as the images change position over time; audio and text are common additional components that can be exploited for retrieval.

Videos are generally organized as a hierarchical structure consisting of, at the lowest level, individual frames (Marchand-Maillet 2000). Contiguous frames from a continuous recording are grouped in temporal order to form shots or segments. Scenes consist of one or more segments grouped semantically where the component segments may not themselves be contiguous. Temporally ordered segments form the video. Segments often mark discrete boundaries and serve as one important unit for information extraction. Importantly, segments can be automatically determined by scene cut detection that recognizes the boundary defined by a significant image change between one or more frames. Such low-level, high-dimension features are not well suited for indexing and retrieval but are practical within the context of an exploratory search user interface. Representative individual images of segments are useful in rapidly browsing a video; by displaying single thumbnail images for each of many selected segments, the complete video can be visually summarized.

IR systems require a means for users to compose queries that relate in an understandable way to the information retrieved. The QBE method, as employed by text searches, provides feedback whereby entering a query word is expected to return results containing that word. QBE video queries, at the most basic level, consist of single frames for retrieving similar videos based on attributes such as color and texture. However, video retrieval can exploit dimensions unique to the media but require novel approaches to the user interface. Motion visual IR can measure object motion and duration over time in addition to the visual features available in static visuals (such as object color, shape, and texture) and associated audio and text. One QBE retrieval system, VideoQ (Chang et al. 1998), exploits spatial-temporal relations by capturing motion and time features from an animated sketch query to match features from a video collection. Videos are automatically segmented into scenes and indexed on attributes that include motion direction, spatial ordering, shape, color, and texture. The user sketches an example scene as a query for which retrieval returns shots from similar scenes from the collection.

The more traditional text IR is also possible on motion videos. The titling and closing segment can often provide textual data for indexing the entire video, whereas speech-to-text translation can provide text for indexing associated video segments.

Issues of Visual IR on the Internet

One analysis of visual IR on the Internet (Kherfi et al. 2004) concludes that it is not currently possible to index the visuals available on the World Wide Web as a result of the number of sources and diversity of media. While even text search engines are outpaced by the growth of the Web, indexing a smaller portion each year, indexing visuals face additional challenges.

The most cited issue facing visual IR, commonly referred to as the curse of dimensionality, stems from the number of visual features and their high dimension. For example, color is one feature but has other dimensions such as saturation and contrast. The need for a large number of visual descriptors is in part due

to the variety of forms visuals take on that include data visualization figures, cartoons, and photographs. Increasing features and dimensionality allows greater discrimination but can quickly overwhelm current indexing techniques. Research has demonstrated (Weber et al. 1998) that sequential search outperforms any other index navigation method when dimension exceeds 10. Research to reduce dimensionality (Rui et al. 1999) suggests ways to eliminate redundant or features with low predictive value.

Audio

Audio IR can be broadly divided into that which has or does not contain speech. Speech provides an opportunity for speech recognition and translation to text, which, as in videos, creates another dimension for indexing and retrieval. When text can be associated temporally with audio, several types of retrieval are possible. The text can be used as a search engine style query to locate audios containing the corresponding speech and retrieve a complete audio much as one would retrieve text documents; at that point the searcher could listen to the audio. However, because speech is linear and inherently temporal, speeding up speech significantly causes listeners to miss content, so that browsing audio becomes problematic. But audio and video are often synchronized and the corresponding text can also serve to access audio in nonlinear patterns to facilitate audio browsing (Amir, Srinivasan, and Efrat 2003).

For audio that lacks speech such as music, features in the time and frequency domain must be exploited for retrieval. Applications include systems that identify audio with similar features and can retrieve the same song performed by different artists given a short example audio query. Purely audio IR is challenging in part as a result of the massive data requirements, one minute of stereo audio in 16-bit pulse code modulation form requires over 10 million data bytes, demanding data reduction and some form of indexing for efficient retrieval to be possible. Other problems are in matching two audio signals of different quality, such as that of a CD and that of a lossy compression. Approaches include some having similarities to text retrieval, in which processing segments of digitized audio features, such as volume, are transformed to code words to form an audio index (Ribbrock and Kurth 2002) for fast retrieval.

As in other media, purely audio queries depend upon existing examples or a means to create one. Musical fingerprinting is an example where the query must exactly match the sought-after recording, a query example from a different performance of the same tune would fail. Music presents a special case of audio having multiple representations that can be exploited for retrieval. For those with some musical expertise, *Meldex* (<http://www.nzdl.org/fast-cgi-bin/music/musiclibrary>) part of the New Zealand Digital Library Project at the University of Waikato (McNab et al. 1997), queries composed through a Web page by musical notation, keyboard, humming, or singing queries will return titles of songs containing similar note sequences. The melody database is in music notation and acoustical queries are automatically transcribed to music

notation for matching. Matching transcribed tunes is analogous to string matching, a logarithmic time operation. However, deviations between the query and database transcriptions as a result of a performer's artistic style or a user's imprecise memory of the tune when sung or hummed preclude exact matching; therefore approximate string matching, a linear time search, is required. For Internet-size tune collections, search time would be prohibitive.

STRUCTURED APPROACHES

We have seen that for every media the lack of structure and the challenge of automatically extracting meaning from low-level features create serious problems for IR in general and, due to scale, Internet IR in particular. We have also seen that the most common approach for making non-text IR tractable is to add text annotation as a form of metadata to describe the actual object; Web-page image captioning is an example. Two fundamental limitations to this approach are that the annotation lacks a controlled vocabulary with which to describe the information and lacks a consistent structure in which to represent the added information; IR indexing and retrieval is then limited to simple text matching of the annotations.

Though many of these IR problems could be addressed by an Internet-scale database system, neither traditional database systems nor the document representations common to the Internet were designed for that task and are unacceptable for several key reasons. Traditional databases represent consistent collections of data having some intrinsic meaning which requires a centralized definition of the data, but a centralized definition of data is too restrictive and runs counter to the distributed nature of the Internet. And most Internet documents, including those written in HTML, lack the structure necessary to organize data in a coherent fashion. Finally, although HTML contains links to other documents, the relationship between the documents is not clearly defined and must be inferred.

Several solutions have been proposed that effectively create an Internet-wide shared database of which MPEG-7 and the Semantic Web are representative examples. Sharing data efficiently and accurately across networks requires a common language for representing information, the most prevalent language basis for data representation and interchange being the extensible markup language (XML).

XML

A common Internet-wide database model is one that is without central control of data definition, which is open to uncontrolled contributions of data, and for which data sources that can be formed ad-hoc as the need requires. The foundational specification and technologies on which most structured Internet IR approaches are based is XML; an application for which XML is well suited. XML itself imposes few syntactical restrictions, allowing new structured data definitions to be created; an important element for a decentralized database. The essential syntax of XML specifies that the data representation be

well-formed, meaning that data be enclosed by a start and matching end tag. The following XML:

```
<Address>
<City>Chicago</City>
<State>IL</State>
</Address>
```

is well-formed; the example also illustrates the hierarchical structure of the data representation. An XML document can be further syntactically constrained through the definition of a grammar defined in document type definition (DTD) or XML Schema format; a parser can then determine if the XML syntax is well-formed and valid for the specified grammar. As an example, the grammar could specify that the `<City>` tag must occur and precede the `<State>` tag.

Technologies and specifications built upon the XML foundation provide the additional elements necessary for developing practical applications that can, as is XML, be network protocol and computer architecture neutral. It is notable that many commercial database systems can translate between internal representation and XML and that database contents represented as XML can be easily shared over the Internet as simple text files. The key contribution of XML to Internet IR and that exploited by the following structured approaches to Internet IR is as a standard of a common foundational language for data representation.

MPEG-7

The Moving Pictures Expert Group (MPEG) developed MPEG-7, an ISO/IEC standard (Martinez 2004), to provide standardized tools for describing multimedia content used in human and machine processing systems. The MPEG-7 goal most relevant to Internet IR is in providing a common basis for applications requiring multimedia content descriptions such as filtering, search, and browsing. The MPEG-7 standard only defines descriptors for multimedia features and does not define how those features are determined or used. However, the standard representation of descriptors does directly support indexing and retrieval of multimedia and data interchange for applications such as electronic program guides and automatic generation of descriptors.

The relevant elements of the MPEG-7 definition to IR are:

- use of reference links to Internet resources,
- feature syntax and semantics descriptors,
- component relationship structure and semantics,
- a description definition language (DDL) to create new or extend existing description schemes,
- coded representations of text and binary in formats for storage and transmission,
- management and protection of intellectual property in descriptions,
- content and descriptor synchronization,
- and multiplexing of descriptions with multimedia content.

The XML Schema language serves as the base of the DDL for MPEG-7 descriptors and description schemes allowing for interoperability with other metadata standards. Descriptors are designed to describe low-level features such as color or texture in visuals or frequency in audio media. Description schemes (DSs) are metadata structures for describing and annotating multimedia content regarding higher-level features such as segments, objects, and creation and production information such as author. Annotation tools assist in manually adding metadata to multimedia, for examples see IBM's MPEG-7 Annotation Tool (<http://www.alphaworks.ibm.com/tech/videoannex>). DSs will, in most cases, be created manually when describing high-level features while some low-level descriptors can be generated automatically; a Web site for automatically generating WAV file audio descriptors is at <http://www.whisper.elec.uow.edu.au/mpeg7>.

Semantic Web

Internet IR based on search engines is limited by the lack of understanding the information it attempts to retrieve. Text implicitly has some meaning, expressing and understanding semantics in other media is less obvious. Over unstructured collections IR is severely limited by the current difficulty in extracting precise semantics to establish an information structure, such as that needed to ascertain relationships between documents or disambiguate words. In multimedia, MPEG-7 was designed to standardize metadata description of low-level features, many of which are automatically extractable, and higher-level descriptions such as annotations, which most often must be created by humans. However, MPEG-7 was not designed for reasoning about metadata (Hunter 2001).

A framework for defining meaningful metadata and inferencing proposed by Tim Berners-Lee is the Semantic Web (Berners-Lee et al. 2001). The Semantic Web vision is a Web where information has an exact meaning and can be easily processed and integrated by machine. The primary goal is to add logic to the Web, expressed in a language for defining data and rules for reasoning about the data, and to answer questions—many of the same questions that text mining also seeks to answer. For example, a simple relationship might define two terms to be synonyms; the relationship might state that the somewhat exotic term of “lady fingers” \equiv “okra” term more commonly used by Americans. Ontologies, which can define relationships among entities, are central to automated data and logic exchange and integration into larger collections allowing, in this case, American recipes for “okra” to be internationalized through the synonym relationship.

The Semantic Web framework includes three key layers with the top layer of uniform resource identifiers (URI) to identify items on the Web and form the foundational syntactical element. A URI can identify anything locally or globally, for example, a uniform resource locator (URL) is a familiar form (e.g., <http://eatmorevegetables.com>) of a URI that identifies a Web site and specifies a location.

A second layer supports an arbitrary data structure that can be defined by individuals using XML, whereas the meaning of the data can be expressed by the resource

```

<?xml version="1.0"?>
<rdf:RDF
  xmlns:rdf="http://www.w3.org/1999/02/22-rdf-syntax-ns#"
  xmlns:hasA="http://Family.Relations">
  <rdf:Description rdf:about="Alice">
    <hasA:daughter>Mary</hasA:daughter>
    <hasA:son>John</hasA:son>
  </rdf:Description>
</rdf:RDF>

```

Figure 12: The RDF statements defining the relationship “Alice has a son John” and “Alice has a daughter Mary”

description framework (RDF). In RDF one can make assertions that data has certain properties through URI triples defining a subject, predicate and object such as a certain person “is an author of” a Web page. With family relationships defined by assertions such as “has a daughter,” one’s family relationship could easily be inferred by a software agent, the data and logical inferences could then be expressed in RDF and XML and shared with other agents. Figure 12 gives the RDF code to define statements “Alice has a daughter Mary” and “Alice has a son John.” The RDF statement consists of the triplet having subject “Alice,” predicate “has a son” and object “John,” each identified by a URI of shared resource located on the Web.

Ontologies form the third key layer to provide shared data structures for information exchange, explicit annotations and knowledge representation; ontologies can be expressed in the Web ontology language (OWL), which is defined as a layer above that of RDF. Ontologies are necessary to the Semantic Web in order to specify the concept of class (things), relationships among things and the properties of things. But how is IR improved? In our simple example, we defined the equivalency relation between “lady fingers” and “okra” that would allow a Semantic Web search engine to index on one term and retrieve on the other. A slightly more clever IR system might return links to the ontologies consulted along with search results so that the searcher could view the document with the ontology relations applied.

Standards are a key element to the Semantic Web’s acceptance and the sharing of Semantic Web data and rules over the Internet; all the components are defined by the World Wide Web Consortium. A number of development tools are becoming available and applications based on the key technologies have been implemented. It is noteworthy in regard to sharing of resources that RFD is also commonly used by other Internet applications such as news aggregators for information interchange and publishing. Another example of an RDF database is The Open Directory Project (<http://dmoz.org/>); a human-edited directory of the Web constructed and maintained by volunteer editors. SWOOGLE is a research project implementation of a Semantic Web search engine (swoogle.umbc.edu). OntoWeb is an example of an ontology based portal (<http://www.ontoweb.org/>). Protégé (<http://www.co-ode.org>) is an interactive development environment for defining and verifying ontologies specified in OWL and other development frameworks are available commercially (<http://www.altova.com>) and as open-source (<http://jena.sourceforge.net>).

CONCLUSION

Ultimately IR must support reaching some conclusion based on understanding; whether directly by a simple existence verification as in copyright identification or an analytical insight based on logically connected information as in a medical diagnosis. For now, Internet IR is primarily defined by search engines and the unstructured text of the Web. Though search engines have brought a remarkable degree of order and access to otherwise unorganized and scattered information of the Internet they have serious limitations. Search engines lack understanding of the semantic relationship between the query and the information they are asked to retrieve leaving that to the searcher to establish. They do not naturally support multiple types of search strategies instead requiring analytical search for all types. They do not generally support multimedia IR except though text search. Finally, ranking methods are influenced more by the implied “Web wisdom” expressed as page links than by recognized expert knowledge. Clearly the future holds great opportunity for advances in these areas.

Some IR problems are a result of the scale of the Internet and may be addressed by distributed IR architectures. Current search engines, though consisting of multiple computers, operate as essentially centralized architectures in which machine resources and tasks are centrally defined. Performing IR of non-text media typically depends upon text IR exploiting either human or machine generated annotations; search engines retrieve images based on nearby text or captioning. Though progress has been made in some areas, such as speech-to-text translation, machine understanding of an image or audio from component features has proven a difficult and continuing problem. Feature extraction, indexing, query processing and retrieval based on low-level media features such as audio frequency or image color are computationally intensive and does not scale beyond restricted collections. Peer-to-peer (P2P) architectures offer the promise of distributing the resources for computational operations and data storage across computers on the Internet, particularly IR on the more challenging non-text media (Sia 2002). Although three standard P2P architectures are generally recognized (Lv et al. 2002), P2P networks can consist of any grouping of interconnected computers without imposing predefined restrictions on their organization or tasks. There are other applications for which P2P networks appear ideally suited, particularly those involving naturally distributed resources such as the shared databases of the Semantic Web (Arumugam, Sheth, and Arpinar 2002).

So what does the future hold for Internet IR? Barring some remarkable progress in machine intelligence, IR of purely text-based unstructured information will continue to be dominated by the current search engine model; though even the search engines will continue to fall further behind Internet growth. IR of other media will progress for specialized and limited applications but is likely to continue exploiting text annotations for indexing and retrieval of Internet-scale information as a result of the high dimensionality of non-text media. Given the recognized benefits, IR based on semantics will expand. Many Internet IR systems can already automatically share information defined within a common representation, eventually the Semantic Web or other coherent information representation structure will spread and grow to achieve a critical mass on the Internet, creating a large collection of information intentionally related. Exploratory search will play a more significant role when tailored to fit with specialized IR applications that enable the searcher to explore information in a more adaptive fashion.

In the not so distant early days of personal computing, each software application stood alone with no natural integration path, not even a clipboard for cut-and-paste operations; application software function took precedence over user interfaces and interaction. Fortunately improved technology and time allowed changes as market pressures forced improvements, particularly in usability. Ultimately, Internet IR will also evolve with other Internet and computer technologies to integrate different media and search strategies through user interfaces that support the essential human requirements in exploring information.

GLOSSARY

- Common log format:** A standard format for logging and analyzing Web server entries.
- DDL:** Description definition language provides for the definition syntactic of MPEG-7 description tools.
- DTD:** Document type definition, part of the XML specification, used to define grammars for restricting the valid syntax of XML documents.
- Exploratory search:** An iterative process of acquiring subject knowledge by collecting and integrating information that leads to further exploration.
- Index:** List of words extracted from pages and the location of each page where the word was extracted. Used for matching query words and locating the pages containing the matches.
- Information retrieval:** Information retrieval has come to be a generic term applied to the access and delivery of information from natural language databases by whatever method.
- Latent semantic indexing:** A method for reducing the dimensionality of a document space to establish a measure of semantic relationship among documents in that space.
- Metasearch:** The fusion of the results from multiple search engines simultaneously searching on the same query.
- MPEG-7:** A Moving Pictures Expert Group (MPEG) standard for describing multimedia content used in human and machine processing systems. Formally

named the “Multimedia Content Description Interface.”

- OWL:** The Web ontology language that defines Semantic Web ontologies.
- Ontology:** A document that defines the relations among terms.
- PageRank:** A system for ranking Web pages where a link from page A to page B increases the rank of page B.
- Precision:** The degree to which a search engine matches pages with a query. When all pages are relevant to the query, precision is 100 percent.
- QBE:** Query by example allows queries to be formulated by providing an example of the expected result.
- RDF:** Resource description framework, a standard representation used to express meaning through URI triples defining a subject, predicate and object.
- Recall:** The degree in which a search engine matches relevant pages. When all relevant pages are matched, recall is 100 percent.
- Relevancy:** The degree to which a page provides the desired information, as measured by the searcher.
- Search engine:** The software that searches an index of page words for query words and returns matches.
- Semantic Web:** A framework for knowledge representation and discovery.
- Similarity:** A measure of how closely the words of a query match the words of a document (page), one means of ranking documents for retrieval.
- Spider:** The software that locates pages for indexing by following links from one page to another.
- Text-mining:** Applying machine intelligence to extract the meaning of information from text.
- URI:** Universal resource identifier used to identify anything locally or globally on the Web, the URL “http://eatmorevegetables.com/broccoli” is one example.
- URL:** Universal resource locator defines the unique location of a Web resource; see the URI definition for an example.
- Vector space:** A representation of each document as a weighted vector in a multidimensional space; the angle between vectors measures the similarity between documents.
- XML:** Extensible markup language, a foundational framework for the specification and representation of structured data.
- XML Schema:** Defines the grammar for restricting the valid syntax of XML documents.

INTRODUCTION

In this chapter, we explore the architectural design of the Internet. We believe that a historic perspective is essential for this exploration. Many important lessons about network design can be learned from the evolution of the Internet architecture. The Internet had a very modest start, borne out of an experimental network with a handful of nodes in the late 1960s. There was no comprehensive theory about packet network design in place at the time. It was not until a dozen or so years later, when the Internet had already become a network with about 100,000 nodes that the broad research community started to realize that several early design choices made for the Internet architecture, with an emphasis on *simplicity*, had played a crucial role in its growth and robustness. (Clark et al. 1988). In other words, it is not by accident that the basic elements of the Internet architecture have withstood the test of time for over three decades, creating the one and only global data networking infrastructure in the process; several architecturally profound design principles were at work. In the first half of the chapter, up to “Security,” we will try to expose as many key points of these design principles as possible while describing nuts and bolts of the Internet architecture.

Examining the Internet architecture from a historic perspective would not be complete without pondering the future of the Internet architecture. In the second half of the chapter, we pose and try to answer the following question: Has the current Internet architecture reached the end of its historical role? To put the question another way: Is a clean-slate design of Internet architecture necessary in order to meet all emerging requirements? We first provide a holistic view of the current Internet architecture based on its division of core functionality into three planes: data, control, and management. We then discuss why the Internet control and management planes have fundamental limitations in coping with several emerging service requirements and why a completely new approach to network control and management may be required. Finally, we describe the 4D network architecture (Greenberg et al. 2005b), which is an instance of a clean slate design of Internet architecture.

For brevity, the discussion will be kept at a high level, with a focus on the fundamental trade-offs behind some of the most important network design choices embodied in the Internet architecture. No complete detail of an individual protocol or mechanism will be provided unless doing so is necessary for the discussion. Almost all important Internet protocols and mechanisms are specified in Internet request for comments (RFCs), a collection of documents that is maintained at the official Web site of the Internet Engineering Task Force (IETF). Interested readers are referred there for more information about a specific protocol or concept.

ORIGIN OF INTERNET ARCHITECTURE

The Internet is easily the largest computer system ever built, with tens of millions of nodes running hundreds of protocols. Examining its architecture is foremost about looking beyond the low-level system components and protocols and identifying the set of *core functionalities* that make it tick. The Internet is essentially a network for transporting digital data (i.e., bit streams) between computer processes. In the most abstract form, a network simply consists of nodes connected by links. In the Internet setting, the nodes are computers and the links are connections between computers. To help illustrate the set of necessary functionalities for providing communication services over the Internet, consider a typical computer communication scenario where process A running on one computer wants to transmit a file to process B running on another computer. For this transmission to be successful, the following functions are required:

- *Data Formatting.* A and B must agree on a common data format so that B can extract and reassemble the content of the file from the bit streams received.
- *Addressing.* Process A must have a means to both uniquely identify B from other processes and supply this identification, called B's address, to the network.
- *Routing.* Methods must be in place for determining a feasible path for moving bits from A to B, based on the addresses of A and B.

- *Forwarding.* Methods must be in place for actually moving bits from A to B, through a predetermined sequence of nodes.
- *Error recovery.* Because no physical transmission medium is perfect and bits may be inverted or lost in transit, algorithms are required to detect and correct these errors.

Equally important is the *division of work*, regarding both the creation of distinct node types and the placement of the aforementioned key functions among the nodes. In one design, the network may consist of homogenous nodes, all of which implement one identical set of functions. Although conceptually simple, this design may be inflexible and/or incur unnecessarily high cost. It is consideration of this kind of design trade-offs that has shaped the development of the Internet architecture.

In this section, we will introduce and briefly describe a set of design principles that have made the Internet architecture into what it is today. Because these design principles started as practical solutions to specific network design problems (Clark et al. 1988), we first look back at history and ground our discussion by laying out the key enabling technologies and the key requirements faced by the architects of the early Internet.

The purpose of introducing the design principles *before* describing the detail of the Internet architecture is twofold. First, we believe that one may appreciate many subtleties of the Internet architecture *better* after having a solid grasp of the big-picture design philosophy of the Internet architecture. Second, as mentioned in the introduction, the focus of this chapter is on the fundamental design trade-offs and thus we would like to start the discussion at a 30,000 foot level.

Enabling Technologies

In the pre-Internet era, the communications technology was dominated by a circuit-based approach used by telephone networks. In circuit-switching the bandwidth of each communication link in the network is segmented into multiple smaller transmission channels called circuits, by utilizing either a frequency division multiplexing (FDM) or a time division multiplexing (TDM) technique (Kurose et al. 2005). Each circuit can only be allocated to one conversation at a time. Because the number of circuits in the network is finite, a call setup process is required before a conversation can start in order to ensure that there are adequate free circuits to form an end-to-end path between the calling parties.

The static allocation of circuits works well for telephony where the network traffic loads are well understood. However, circuit-switching would cause a significant waste of bandwidth when used to transport computer data traffic such as from a telnet session, which typically is very bursty with long periods of inactivity. This problem motivated people to seek an alternative approach to building networks for linking computer resources, which led to the invention of the *packet-switching* technique in the early sixties (Internet Histories 2006).

In the packet-switching approach, computer data (i.e., bit streams) are transported in small chunks called packets.

The capacity of a communication link is not segmented; packets of different users take turns being transmitted at the full link rate. This form of dynamic sharing of the whole link capacity among different connections, termed *statistical multiplexing*, ensures no waste of link bandwidth as long as there are packets to be transmitted.

Statistical multiplexing requires the use of buffers to hold packets waiting for their turn to be transmitted. This type of buffering naturally led to the birth of a “store and forward” communication paradigm in which packets may be forwarded on a hop by hop basis toward their destinations. Under this paradigm, it is also very easy for intermediate nodes to independently adjust routes that packets take based on current network conditions. Such a dynamic routing capability was quickly recognized as a desirable function of a computer network for resisting link or node failures in the network even before the first packet network was ever built (Internet Histories 2006).

Driving Requirements

The Internet began as an experimental network called ARPAnet, which was sponsored by the U.S. Department of Defense (DoD) initially for testing the viability of packet switched computer networks and later for demonstrating ways of combining packet networks that use different link technologies (leased phone lines, satellite, radio, etc.) into one integrated data communications infrastructure for the military (Internet Histories 2006). High on the requirement list for the Internet project were:

1. **Robustness:** Because of the military sponsorship, an emphasis is put on the ability of the network to continue to operate in the presence of link or node failures.
2. **Link heterogeneity:** Also important to the military is the network's ability to rapidly assimilate different link technologies so the network can be quickly deployed and extended.

Other requirements for the Internet architecture included the support for multiple types of communications service and distributed management of network resources (Clark et al. 1988). Surprisingly, both network security and quality of services (i.e., performance guarantees) are not in the original list of requirements for the Internet. The reason is simple: ARPAnet was originally envisioned as a private data network for the U.S. military and, as such, security was considered more of a physical layer concern and quality of services deemed a non-issue with the assumption that traffic entering the network would be carefully planned resulting in a lightly loaded network at all times.

Design Principles

To meet the overriding requirements of robustness and link heterogeneity, the original architects of the Internet made two important design decisions regarding how to organize the core computer networking functionalities. First they recognized that a monolithic network architecture where each switching node can cope with all link

technologies will not scale (Clark et al. 1988). The concept of adding specialized packet switching nodes, called Internet message processors (IMPs), to the network architecture was developed to address that problem and to take advantage of the then new store-and-forward communication paradigm. Each IMP, which we call a gateway or router today, would be an intermediary linking two or more different packet networks. A three-part address format was defined: one for identifying a communicating process, another for identifying the process's host computer, and the last one for identifying the host network. A packet would carry both source and destination addresses in its header. A gateway would only need to inspect the network portion of the destination address when making packet forwarding decisions. Once a packet arrived at the destination network, that network would use the other parts of the destination address to deliver the packet to the receiving process (Cerf et al. 1974; Living Internet 2006).

The use of packet-switching gateways not only greatly *simplified* the task of establishing connectivity between independently managed networks with heterogeneous link technologies, but also enabled the store-and-forward paradigm, under which dynamic routing of packets in transit could be done transparent to the communicating processes. However, this design had a distinct performance disadvantage compared to a circuit-switched network: no guarantee of quality of service. Although aware of the disadvantage, the Internet architects made a conscious decision to choose simplicity over efficiency. This design choice since has become an overarching design philosophy for the Internet:

Simplicity over efficiency: *Whenever possible, trade efficiency for simplicity.*

The second far-reaching design choice made by early Internet architects can be thought of also as a practice of the “simplicity over efficiency” principle, although with a little twist. Initially, one “super” protocol that combines routing, packet forwarding, and end-to-end reliable delivery functionalities was developed to provide the communication service for all applications (Cerf et al. 1974). After closer examination, the Internet architects realized that reliable service may not be a good fit for some applications, for example, one that exchanges real-time voice traffic, to which timeliness is much more important and for which retransmissions are counterproductive by incurring extra latency. This observation inspired the concept of having the network core provide *minimal* packet level forwarding service, upon which different types of data communication services including reliable data transfer would be built at the end hosts of the network. Following this concept, the forwarding functionality was extracted out of the super protocol and made into an independent Internetworking Protocol (IP). Two types of end-to-end communication services were then defined over IP: (i) user datagram protocol (UDP) which provides just an end multiplexing point for IP packets of different application processes running on the same host; and (ii) transmission control protocol (TCP), which has added functionality to support reliable data transfer.

By treating packets independently and forwarding them based on their destination network address, the IP protocol does not require the gateways to maintain any connection state about application processes. This flexibility has greatly *simplified* the design of gateways, the main piece of the technology puzzle for connecting new networks into the Internet, and therefore should be considered one of the crucial factors for the rapid growth of the Internet. Throughout the years, the Internet architects have upheld this design choice of a “thin” Internet-working layer, resulting in the following design principle for division of functionalities required for building communication services over the Internet:

Datagram service: *Provide simple connectionless packet forwarding service in the network core.*

The minimalistic approach to gateway design was later justified and generalized into the so called end-to-end argument for placement of functions among modules of a distributed computer system (Saltzer et al. 1984). The argument can be stated succinctly as below (Saltzer et al. 1984):

End-to-end argument: *Functions placed at low levels of a system may be redundant or of little value when the cost of providing them at the low level is factored in.*

The Internet is a distributed system with two levels of functionality: the network subsystem at the lower level providing communication services to application clients at the upper level. Under the end-to-end argument or design principle, networking functions that deal with network anomalies such as bit errors, node crashes, packet duplications, buffer overflow, would be best implemented at the end hosts where application client processes reside, particularly when the occurrences of anomalies are too infrequent to make it cost effective to place corrective functions inside the network (Saltzer et al. 1984).

CURRENT INTERNET ARCHITECTURE

Today, the Internet has evolved from a U.S. military system prototype into an open, world-wide infrastructure over which a rich set of applications, including Web, E-business, voice over IP (VoIP), video broadcast, and online gaming, is deployed. These applications have imposed additional performance and security challenges on the network. New elements have been incorporated into the Internet architecture in an attempt to address these challenges. In this section, we delve into the major building blocks of the Internet architecture: describe their *current* functionality and trace their evolution path.

Data Formatting

In the Internet, all types of digital information are encapsulated in packets with a standard format defined by the IP protocol (RFC 791). At a minimum, a host needs to be able to send and receive packets in that format in order to be connected to the Internet. As discussed in

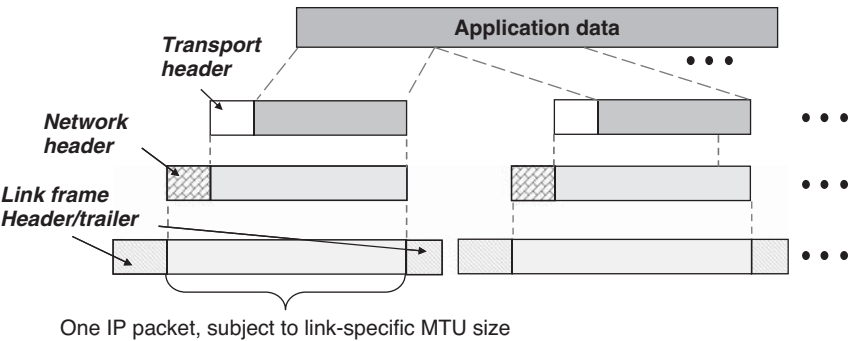

Figure 1: Packet encapsulation; from a router’s perspective, all types of application data are encapsulated in IP packets; these packets are delivered using different link-layer technologies hop by hop

“Design Principles,” two types of end-to-end communications service (or transport protocol), TCP and UDP, have been defined on top of IP. Moreover, each application has its own set of agreements on the message format and the method of exchanging these messages. For example, a Web browser uses the hypertext transfer protocol (HTTP) protocol (RFC 1945; RFC 261) to communicate with a Web server. Therefore, the packaging of application data into IP packets at an end host involves several layers of encapsulation, as described below.

Packet Encapsulation

Figure 1 illustrates the typical packet encapsulation process at an end host. The “Application data” box represents the sequence of bits for an application-specific message (e.g., an HTTP message requesting a Web page) that is to be sent from the host. In the first encapsulation step, the message is encapsulated in *one or more* transport-layer segments with the same TCP or UDP header (see RFC 793 and RFC 768, or a networking textbook such as Kurose et al. (2005), for details about TCP and UDP). In the next step, each transport-layer segment is encapsulated in an IP packet by prepending an IP header. In the final step, a link-layer frame is created by prepending an additional header and possibly a trailer. The link-layer frame format may vary from network to network, specific to the link layer technology used in each network. For example, the Ethernet format would be used here if the host were part of a local area Ethernet network. It should be noted that the link-layer header and trailer will be removed before the packet is passed to router modules that make routing and forwarding decisions.

Also, each link-layer technology defines its own maximum transfer unit (MTU) parameter: the maximum number of bytes that can be encapsulated in one frame. For example, the MTU size for the Ethernet protocol is 1500 bytes; therefore, the size of an IP packet cannot exceed 1500 bytes in an Ethernet environment. That’s why the application message may have to be encapsulated in multiple transport layer segments.

Because there is not a standard MTU size across all link-layer technologies, it may also happen that an IP packet is forwarded to a network with an MTU smaller than the packet’s size. Should the packet be discarded or fragmented into multiple packets of an appropriate size? We defer this topic to “Dynamic Routing” after we have a chance to inspect the IP header format.

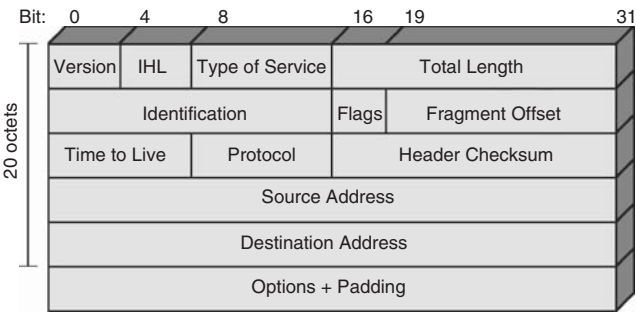

Figure 2: IP header format. [Figure 18.6 of Stalling04] Each row represents a 4 byte word. The total length is always a multiple of 4 bytes after possible padding

IP Header Format

Figure 2 shows the IP header format. The individual fields are defined as follows (RFC 791):

- *Version*: a 4-bit value indicating the version of the IP protocol used. Currently, we are at version 4, abbreviated as IPv4. Some experimental networks are running IP version 6 (IPv6). We will briefly discuss the features of IPv6 in “NAT and IPv6.”
- *Internet Header Length (IHL)*: a 4-bit value indicating the length of the IP packet header (including all the option fields and padding), in 4-byte words. For example, a packet with a 24-byte long header would have this field set to 6.
- *Type of Service (ToS)*: an 8-bit value indicating the quality of service desired for the packet. This field had not been widely used until the differentiated service (Diff-Serv) model was introduced in the mid-1990s. We will briefly discuss DiffServ in “Integrated Services Model.”
- *Total Length*: a 16-bit value indicating the total length of the IP packet in bytes, including the header and the data payload encapsulated in the packet.
- *Identification, Flags, and Fragment Offset*: These fields are used by the IPv4 fragmentation and assembly algorithm, which we will describe in the next subsection.
- *Time to Live (TTL)*: an 8-bit value representing an upper bound on the number hops (routers) that the packet can still traverse. Any router module that forwards packets must (i) decrement each packet’s TTL field by at least one and (ii) discard a packet with a zero TTL value. The

intention is to cause undeliverable packets to be discarded, and to place an upper bound on the maximum packet lifetime. Upon discarding a packet with a zero TTL, the router will notify the sender of that packet of this action via the Internet Control Message Protocol (ICMP). (ICMP is defined in RFC 792.)

- *Protocol*: an 8-bit value identifying the next level protocol that is encapsulated. The id's for various protocols, called protocol numbers, are specified in RFC 790. For example, the protocol number for TCP is 6.
- *Header Checksum*: 16-bit one's complement of the 1's complement sum of all 16-bit half-words in the header. For purposes of computing the checksum, the value of the checksum field is zero.
- *Source Address and Destination Address*: 32-bit addresses for the source and destination network interfaces, respectively. The specifics of the IP addressing scheme will be examined in the next subsection. It should be noted that an end host may have multiple network interfaces; in that case, this host is said to be "multi-homed" and any one of the interfaces can be used to reach an application running on this host.
- *Options*: The field may specify the presence of optional IP functionality. One of the existing options is source routing, whereby a predetermined sequence of routers that must be traversed by the packet can be specified.

In summary, the IP header format is quite simple, reflecting the desire for imposing minimal requirements for connecting new hosts into the Internet. In accordance with the datagram service, no header fields are provided for recording session-specific state and each packet is required to carry destination address information.

Packet Fragmentation and Reassembly

The "Identification" field in the IP header is designed to give a unique identifier to each packet upon its generation at a host. Different host operating systems (Windows, Linux) may use different algorithms for setting this field. Most commonly, the value is derived from reading the host's system clock. When the packet encounters a network with an insufficient MTU size and thereby needs to be fragmented, that is, broken down into several smaller packets, the same identifier is inherited by all the fragments. Additionally, the 13-bit "Fragment Offset" field of each fragment packet is calculated based on where the first byte of the fragment is situated, in length of 8-byte double-words, relative to the start of the original packet. One of the bits of the "Flags" field, the More Fragments (MF) bit, is set for all fragments except the last one. This information allows the receiving host to identify and assemble the fragments back into the original packet. It is possible that these fragment packets need further fragmentation at another network with an even smaller MTU. However, reassembly is done only once for the packet at the receiver.

The IP protocol allows the fragmentation/reassembly feature to be turned off by setting another bit of the "Flags" field, the so-called Don't Fragment (DF) bit. When that bit is set, the packet would be dropped under the scenario described in the previous paragraph. Additionally, the router

that dropped the packet would send an error notification message to the sender of the packet via ICMP.

The design of the IP fragmentation/reassembly functionality can be viewed as an application of the "Simplicity over Performance" principle. It certainly has a negative performance impact on the routers that have to perform the checking and the fragmentation. But it avoids imposing a standard MTU size on every link technology and thus removes a potential barrier for connecting a new type of network into the Internet. Instead, a minimum MTU is instituted, which is 576 bytes for the current version of IP (version 4) and 1280 bytes for IP version 6.

Addressing

The basic approach of the three-level hierarchical addressing scheme as described in "Design Principles" remains unchanged through the years. More specifically, the process portion of the address definition, called *port*, has been standardized as part of both TCP and UDP header formats, and the network and host portions of the address definition have been combined into one 32-bit value, called *IP address*, which should be globally unique. For ease of writing, an IP address is usually represented in the so-called dotted-decimal form, in which the 32 bits are partitioned into four bytes written in their decimal form and separated by a period (dot). For example, "192.128.10.168" is the IP address assigned to the network interface installed on the laptop that I have used to write this chapter.

Subnet and Subnet Mask

As shown in Figure 3, an IP address is composed of two continuous blocks of bits. The left block contains the "Network bits" and identifies the home network (or subnet) for the host. All network interfaces in one subnet should be assigned the same block of network bits, called the *subnet prefix*. The right block contains the "Host bits," which should be uniquely assigned to each network interface installed on a host in the subnet.

To reduce the size of the forwarding tables at routers, routing in the Internet is done based on matching subnet prefixes instead of matching the entire 32-bit addresses. Accordingly, one or more gateway routers should be attached to each subnet. The Internet routing and forwarding algorithms are only responsible for transporting packets to these gateways, which then deliver the packets to the receiving hosts (or more precisely, the network interfaces of these hosts) using a technology specific link protocol. Similarly, packets destined for a remote host (i.e., not in the same subnet as the sending host) also have to depart through the gateways.

Clearly, a method for determining the boundary between the network and host blocks of an IP address is required for extracting the right subnet prefix. For example,

Figure 3: IP address layout

“192,” “192.128,” “192.128.10,” are just a few of the possible subnet prefixes for the IP address “192.128.10.168.” The original solution was to define several classes of network prefixes, each with a unique starting bit pattern, and then assigning a fixed number of network bits per class. Specifically, class A network prefixes start with binary “0” and always have 8 network bits. Therefore, there are a total of $2^{32-8} - 2 = 16,777,214$ unique addresses to assign to its network interfaces. Class B network prefixes start with binary “10” and always have 16 network bits. Finally, class C network prefixes start with binary “110” and always have 24 network bits.

Later, the class-based network assignment was found to be inflexible and wasteful in terms of the percentage of addresses actually assigned per network. For example, a company with a dozen of employees would be unlikely to fully utilize even a class C network address space that contains $2^{32-24} - 2 = 254$ valid host addresses. The subtraction of 2 is needed because two special addresses are preconfigured for each subnet and not available as host address: one for broadcast, with all host bits set to 1, and the other being the subnet id, with all host bits set to zero. The current solution is to allow subnets of any size and to require each subnet to explicitly declare the exact number of network bits that it is assigned. For example, the subnet where my laptop is located has a prefix of “192.128.8.0/22.” The “/22” notation indicates the prefix is made of 22 network bits. “192.128.8.0” is the *subnet id* and is obtained from zeroing out all the host bits (i.e., the rightmost 10 bits) in “192.128.10.168.” The zeroing step can be easily accomplished by a bit-wise AND operation between “192.128.10.168” and a special address “255.255.252.0,” which is obtained by setting all the network bits and clearing all the host bits. This special address is called the *subnet mask*. Under this scheme, a router can easily determine if a given destination address matches one of the network prefixes in its forwarding table: for every network prefix in the table, first calculate a subnet id value for the IP address using the prefix’s subnet mask and then match it against the subnet id for that prefix.

DNS and DHCP

Even in the dotted decimal form, IP addresses are not easy for humans to remember. Also, *manually* configuring every network interface with the right combination of IP address, gateway address, and subnet mask can be a challenge for a large network with hundreds of hosts. Fortunately, two protocols have been developed to help us with these tasks.

The domain name service (DNS) protocol allows an application to refer to a host by its fully qualified domain name (FQDN), which is also in a dotted format, albeit with words in a string format, not decimal numbers. For example, the FQDN of my laptop has been set to be “xielap.cs.nps.navy.mil,” which is a lot easier to remember than “192.128.10.168.” “xielap” is the *host name* chosen by myself, whereas “cs.nps.navy.mil” is the name for the *network domain* of my work place: Department of Computer Science of Naval Postgraduate School. The “.” operator in an FQDN denotes the *part-of* relationship: “cs.nps.navy.mil” is part of the “nps.navy.mil” domain, “nps.navy.mil”

is part of “navy.mil,” and so forth. All network domains can be thought of being part of a root domain. A network domain may contain multiple subnets and subnets of the same domain are typically administrated by one domain authority. Since the IP protocol does not recognize FQDNs, DNS provides applications a service that translates an FQDN into its IP address counterpart, and vice versa. Each domain authority is responsible for setting up a DNS server that maintains a mapping between the FQDNs and IP addresses of all local hosts in its domain and answers queries about the mapping from either an application running on a local host or a remote DNS server on behalf of a remote application. A detailed specification of the DNS protocol is given in RFC 1035.

The dynamic host configuration protocol (DHCP) supports auto-configuration of a network interface. To enable this feature on a subnet, one must set up a DHCP server and assign to it a pool of free IP addresses for that subnet. When a host in the subnet is booted up, it will use broadcast to reach, maybe via a relay agent, the DHCP server and request an IP address and other information required for configuring its network interface. In response, the server will typically remove an address from the free address pool and allocate it to the host for a fixed duration. The host will contact the server to renew the allocation periodically when it stays up for a long time. The host may also contact the server to explicitly return its address to the pool of free addresses, for example, when the host is being shut down. A detailed specification of DHCP can be found in RFC 951.

NAT and IPv6

In the mid-1990s, as a result of years of explosive growth of the Internet, a crisis of IP address shortage seemed looming. Theoretically, the 32-bit address space provides close to 4 billion unique addresses. However, even with classless network allocation, a significant percentage of allocated addresses are unused and thus wasted. Also, many addresses are reserved for special purposes: broadcast, multicast, private, and so on, and not available for hosts. Therefore, when people started to talk about connecting everything, from cell phones to toasters, to the Internet, it was perceivable that the pool of unallocated IP addresses could soon run dry. In response to this crisis, two major solutions were proposed. One was supposedly a near-term fix which requires no change of the current IP address format and the other was touted as a long-term solution which changes the address format to make it 128-bit long.

The near-term solution is called network address translation (NAT), specified in RFC 1631. In this scheme, a network’s external connection must go through a NAT server. The server replaces the source address and source port pair of every outgoing packet with its own IP address and a “surrogate” source port that is unique to a specific source address and source port combination. In other words, there is a one-to-one mapping between a source address and source port combination to a “surrogate” port. The NAT server records such mappings in a hash table keyed by the value of the “surrogate” port. The server also inspects every incoming packet, uses the packet’s destination port field as the key to find the right

address mapping for the packet, overwrites the destination address and destination port fields with the ones obtained from the mapping, and finally forwards the packet on inside the network. Thus, it is not necessary to assign globally unique addresses to hosts inside the network. A common practice is to use private address ranges for these hosts. Only the NAT server needs to have a globally unique address, making NAT an effective solution for mitigating the address shortage problem.

The long-term solution requires upgrading the IP protocol (version number 4) to a new version, IP version 6 (IPv6). In addition to a drastically larger address space than IPv4, IPv6 also includes new features such as auto-configuration and a streamlined header structure. Interested readers are referred to RFC 2460 and (Davies 2002) for details about IPv6.

Dynamic Routing

Routing in the context of the Internet is about maintaining consistent forwarding tables at the routers, in accordance with the network's store and forward communication paradigm. In the early days of the Internet, routing was not a major issue because of the small number of networks connected to it. Routing within a network was often done with a private protocol and routes between networks were static and manually set up (Clark et al. 1988). Later, as the size of the Internet grew, it was no longer possible to assume a static topology, and dynamic routing became necessary.

Before we delve into routing, let's briefly look at how forwarding is done given consistent forwarding tables at all routers. As mentioned in "Subnet and Subnet Mask," the forwarding is done by matching subnet prefixes. A typical forwarding table at a router, often referred to as the Forwarding Information Base (FIB) for the router, contains entries (i.e., routes) in the format of: <network prefix>, <next hop>, <metric>. <network prefix> is the subnet prefix of the destination network for this route, <next hop> the interface to use as part of this route to reach the destination, and <metric> a measure of goodness of this route. To forward a packet, the router first looks up its FIB with the packet's destination address and searches for subnet prefix matches using the method described in the end of "Subnet and Subnet Mask." When the packet's destination address matches multiple routes in the FIB, the router chooses the route with the *longest prefix match*, i.e., with the most matching network bits. If there are more than one longest prefix matches, the router uses the <metric> field to break the tie. After determining a route, the router forwards the packet to the output port as defined by that route's <next hop>.

Hierarchical Organization of Networks

To scale to millions of networks, a two-level routing hierarchy has been defined for the Internet, analogous to the "first state, then city, and finally street" way of delivering mail by the post offices. At the top level, routing is done among network domains. Each domain is designated as an autonomous system (AS) and assigned a unique 16-bit *AS number* for routing purposes. For example, my

school's domain "nps.navy.mil" is also AS 257. Currently, there are about 30,000 active ASes in the Internet. At the bottom level, within an AS, routing is done between routers inside that AS. This "divide-and-conquer" approach ensures that each router only needs to maintain a relative small number of routes in its FIB. The largest FIB reported has about 200,000 entries, which is a lot smaller than the total number of subnets in the Internet.

Because ASes are independently administrated, different intra-domain routing protocols may be deployed in different ASes. This is not the case for inter-domain routing; all ASes must implement the same inter-domain routing protocol to achieve full interoperability.

Intra-Domain Routing

Typically, a single administrative authority has total control over all routers in an AS. Such control makes it possible to consider additional performance objectives when designing intra-domain routing protocols. The current generation of intra-domain routing protocols are designed to rank routes based on a distance metric defined as follows. First, each link connecting two subnets is given a cost metric. The distance of a route is the sum of the costs of all links traversed by that route. The simplest definition of link cost would be assigning a value of "1" to every link. In that case, the distance of a route would be its *hop count*, that is, the total number of links it traverses. In summary, an intra-domain routing protocol is about computing shortest paths between all pairs of subnets within an AS.

Two classes of protocols have been developed for dynamically computing shortest paths between routers: *distant vector* and *link state*. A distant vector protocol is totally distributed, based on *iterative* computation of shortest paths. A router only communicates with a direct neighbor and exchanges updates on each other's distance vector, that is, a table of current minimum distance to all known destinations. A neighbor's update message may trigger a new update at the router following the iterative Bellman-Ford algorithm. Much like human gossiping, the router will eventually know about every other router in the network, the correct minimum distance to it, and the neighboring router to use to achieve that minimum distance. Routing information protocol (RIP), one of the earliest dynamic routing protocols designed for the Internet and currently at version 2 (RFC 2453), is a primary example of distance vector routing protocols.

A link state protocol is centralized in the sense that each router will first obtain a *global* view of the network, including topology and link costs, through flooding of link state packets by all routers and then *independently* apply the Dijkstra's algorithm to compute the shortest paths. If all routers have the same global view, then the FIBs built by the routers will be consistent. Upon a change in the network topology or link cost, the affected router(s) will flood new link state packets to update the global view at each router and trigger new shortest path computation. Open shortest path first (OSPF) and intermediate system-intermediate system (IS-IS), specified in RFC 2328 and RFC 1142 respectively, are the two most prominent link state routing protocols.

Inter-Domain Routing

The AS-level topology is a mesh, with each AS having connectivity with one or more other ASes based on business agreements. Because ASes are independently managed, there is no uniform scale for the link cost metric across different ASes. So determining the distance between two ASes based on adding link costs is not very meaningful. Instead, policy is more important in inter-domain routing. For example, an Internet Service Provider (ISP) may choose to avoid a particular AS (belonging to a competitor) in all its routes. To assist policy based routing, the Internet uses a *path vector* protocol called border gateway protocol (BGP) for inter-domain routing (RFC 4271). Each AS sets up one or more BGP border routers for exchanging path vectors, each of which is a full sequence of ASes to use to reach a specific destination network, with border routers of neighboring ASes. In general, an AS will advertise a route learned from one neighbor to other neighbors after appending its own AS number to that route. Policy-based actions may be specified in three stages of BGP operation at a border gateway. First, import filters may be placed to reject certain routes received from a neighboring AS. Second, policy may be defined regarding how multiple imported routes for the same destination are ranked. Third, export filters may be placed to restrict the scope of route advertisements to neighboring ASes.

Resource Allocation

Resource allocation did not receive serious consideration in the original design of the Internet architecture because of the datagram service principle. However, as the reach of the Internet extends and the access speed increases, latency or loss sensitive applications such as video phone start to be deployed. These applications require the network to provide some minimum level of performance guarantee with respect to throughput, packet delay, packet loss rate, and so on. A new catch phrase, quality of services (QoS), has since been coined by the networking community to refer to the level of performance guarantee a computer network provides.

Although some people still view over-provisioning, that is, making bandwidth so abundant that link congestion is unlikely, as a viable solution to all QoS problems, both the network research and operational communities have recently explored alternative solutions aimed at avoiding link congestion through elaborate resource allocation schemes. These efforts are described below.

Traffic Engineering

Traffic engineering involves adapting the flow of packets through the network based on a given set of performance objectives and the traffic matrix, that is, the observed *typical* volume of traffic from each ingress point to each egress point. Often, a network designer needs to deal with conflicting performance objectives, such as minimizing the maximum link utilization and bounding the propagation delay between each pair of routers. Satisfying them simultaneously for a dynamic network environment is very challenging under the current Internet architecture. A good commentary on the existing traffic engineering

approaches is given in (Rexford et al. 2004), which we will quote below:

“Early attempts to engineer the flow of traffic involved extending the routing protocols to compute load-sensitive routes in a distributed fashion. In these protocols, the cost of each link is computed as some (possibly smoothed) function of delay or utilization, in order to steer packets away from heavily-loaded links. However, routing oscillations and packet loss proved difficult to avoid, since routers were computing routes based on out-of-date information that changed rapidly, and the effort was eventually abandoned. To improve stability, the distributed algorithms were extended to compute a path for groups of related packets called *flows*. These load-sensitive routing protocols can have stability problems as well, unless the dynamic routing decisions are limited to aggregated or long-lived flows. Perhaps more importantly, the protocols require underlying support for signaling and distributed algorithms for optimizing paths for multiple metrics.

Many existing IP networks have instead adopted a centralized approach for engineering the flow of traffic using traditional IP routing protocols (e.g., OSPF). In this scheme, the management plane collects measurement data to construct a network-wide view of the offered traffic and the network topology. Because the optimization of the OSPF weights is an NP-complete problem, the management plane conducts a local search through candidate settings of the link weights, looking for a solution that satisfies the various performance objectives. Considering additional performance metrics is as simple as changing the objective function used to evaluate the solutions. However, this approach has its limitations in satisfying different metrics for traffic to different destinations, and for avoiding disruptions during failures and planned maintenance. Ultimately, having a single integer weight on each link is not sufficiently expressive, though this approach has proven very useful in practice.”

Integrated Services (IntServ) Model

In the early 1990s, the network research community made a serious attempt to extend the datagram service model and retrofit a QoS solution over the Internet. The effort was motivated by the seminal work of Parekh and Gallager, which shows that the end to end delay of one application's packets can be upper bounded regardless of the behaviors of other applications if an appropriate packet scheduling algorithm, such as packetized generalized processor sharing (P-GPS) or weighted fair queuing (WFQ), is used at every output link that the packets traverse. The new service model was named integrated services (IntServ) after its lofty goal to meet the QoS requirements of all types of application data including interactive audio and video (RFC 1633). The core of the service model is a new type of service called “guaranteed service,” which provides a deterministic (i.e., for 100% of the packets) guarantee of performance, in terms of maximum

end-to-end packet delay and minimum throughput, on a per application basis. All packets for an application that has subscribed to this service traverse the same set of links, and are referred to as a *flow*. The flow has a separate buffer at each output link and receives a guaranteed rate of service from the packet scheduling algorithm based on the flow's bandwidth requirement. Clearly, in order for the guaranteed service to work, the application must reserve network resources (link bandwidth, buffer) along a network path ahead of time. A protocol called RSVP (resource ReSerVation Protocol) has been developed to facilitate this task. RSVP is specified in RFC 2205.

Differentiated Services (DiffServ) Model

IntServ is elegant in theory. However, the research community soon realized that IntServ might not be able to scale to the size of the Internet because it requires per-flow state to be maintained at all routers, including the backbone routers which may have to deal with millions of flows concurrently. An alternative solution was quickly developed. The solution centers on a differentiated service (DiffServ) model, in which only inter-class *performance differentiations* are guaranteed over a small number of service classes. Neither per-flow nor absolute, quantitative service guarantees are provided. Three DiffServ service classes have been well defined, in the order of increased performance: default forwarding, which is the same as the default best-effort service offered by the Internet, assured forwarding, which ensures a sustained throughput, and expedited forwarding characterized by low loss, low delay, and low jitter. It is up to each network provider (ISP) to choose particular packet scheduling and queue management algorithms at each of its routers to support the required per-hop forwarding behaviors (PHBs) for the defined service classes.

DiffServ achieves scalability by implementing complex classification and conditioning functions (metering, marking, shaping, and policing) only at access routers at the edge of the Internet. These functions are carried out based on the service level agreements (SLAs) between network customers and providers. The core routers need to allocate buffer and bandwidth only on a per service class basis while applying PHBs to aggregates of traffic which have been appropriately conditioned and marked using the ToS field in the IP header by edge routers. The details of DiffServ can be found in RFC 2474 and RFC 2475.

Multi-Protocol Label Switching (MPLS)

MPLS is the latest attempt of the computer networking community to retrofit a connection-oriented forwarding service over the Internet. Such a forwarding service not only is conceptually appealing and but also streamlines resource allocation. Strictly speaking, MPLS is not a network layer protocol; it operates between the link and network layers and independently of the IP protocol. It is called "multi-protocol" because its 4-byte header format has been incorporated into the frame headers of different link technologies. For an Ethernet link, the header is simply appended to the front of an Ethernet frame. For an ATM link, the 32 bits of the ATM cell header fields, virtual path id (VPI) and virtual circuit id (VCI), are redesignated to carry the MPLS header fields. The MPLS header contains mainly a 20-bit "label" field, which serves

as a connection ID and a 3-bit "class of service" (CoS) field for support of QoS differentiation. A label switching router (LSR), one that is able to process MPLS packets, will use this label to make the forwarding decision and bypass the IP header. The LSR will also overwrite the label with a new value that is anticipated by the downstream LSR. That is why the protocol has "label switching" in its name. All the label values are determined ahead of time as part of the MPLS connection (tunnel) set-up process performed by a label distribution protocol (LDP).

MPLS is mostly used by an ISP as a local traffic engineering solution, often combined with DiffServ mechanisms. Typically, a set of MPLS tunnels is preconfigured within the ISP's network. The ingress routers of the ISP classify all arriving packets based on their header fields, and insert corresponding MPLS header fields at the output link for those classified to be transported by one of the MPLS tunnels. More information about MPLS can be found in RFC 3031.

Security

For the reason explained in "Driving Requirements," security was not high on the original list of goals for the Internet. Today, with the Internet becoming an open infrastructure for e-commerce and e-government, security is one of the most pressing issues faced by the Internet community. Several security mechanisms such as firewall, virtual private network, transport layer security, secure email, and public key infrastructure (PKI), have been added to the Internet architecture with some level of successes. Two of them are described below.

Firewall

A firewall is a combination of specialized hardware and/or software acting as a network's *security gate* that can restrict types of communication between the network and the public Internet, mainly to prevent unauthorized access to the network's resources. Typically, a firewall administrator has configured the firewall with a set of packet filtering rules based on security policy. The firewall inspects the header fields of all packets that come in and out of the network and drops those matching the filtering rules. For example, a firewall may only allow Web traffic to come in the network by filtering out all packets that don't carry an HTTP payload. A firewall can also be *stateful* in that it will try to enforce certain communication patterns involving several packet exchanges. For example, a stateful firewall will deny a TCP connection response (so-called TCP SYN-ACK message) from coming in if it has not seen a corresponding connection request going out.

Virtual Private Network (VPN)

Often an organization spans multiple geographical locations. It's very expensive for this organization to build a private data network with leased lines to connect all its sites. An alternative approach is to use the public Internet for connectivity and rely on additional security protocols for data privacy, resulting in a virtual private network (VPN). Currently, most VPNs are built by setting up a VPN proxy between each site network and the Internet. The proxies run a tunneling protocol that allows packets for this VPN to be encrypted and encapsulated

with additional headers at the proxy of the source site and then decrypted and de-capsulated at the proxy of the destination site. By treating the network core as a black box, VPN is a design based on the end-to-end argument. There are two types of VPN tunneling protocols: some, like L2TP, run at layer 2 (link layer), and the others, like IPsec, run at the layer 3 (IP layer). L2TP and IPsec are defined in RFC 3931 and RFC 4301, respectively.

In summary, the current security techniques for the Internet focus on establishing a security perimeter around a network and preventing unwanted traffic from coming in. Very little can be done to defend against attacks originated inside the security perimeter. It is also very difficult to verify if the security perimeter has been properly configured or if the security perimeter will hold in the event of link or node failures (Xie et al. 2005).

FUTURE OF INTERNET ARCHITECTURE

Starting from this section, we will look forward and examine the future of the Internet architecture. Several stirring proposals, such as Clark et al. (2003) and Greenberg et al. (2005b), have come out recently calling for a clean slate design of the Internet architecture. Regardless of whether they will stand the test of time, these proposals constitute serious efforts aimed at understanding the limitations of the current Internet architecture and seeking future directions in network design. As a result of space constraints, the rest of the discussion will be based mainly on one of them, called the 4D architecture (Greenberg et al. 2005b, 2005c).

The 4D architecture was conceived by a team of researchers from Carnegie Mellon, Princeton, AT&T Research, and Naval Postgraduate School, including the author of this chapter. The 4D architects argue that the current Internet architecture has reached the end of its historical role because it does not have intrinsic capacity to meet emerging QoS and security requirements and the bandage solutions such as presented in “Resource Allocation” and “Security” are creating an even bigger problem by inducing bewilderingly high network management complexity (Greenberg et al. 2005b).

To better understand this argument, let’s introduce another abstraction of the Internet architecture based on the time scale of execution of its constituent functions. Specifically as described in Rexford et al. (2004), the current Internet architecture can be decomposed into three planes:

Data plane: The data plane is local to an individual router, or even a single interface card on the router, and operates at the speed of packet arrivals, *down to nanoseconds per packet*. For example, the data plane performs packet forwarding, including the longest-prefix match that identifies the outgoing link for each packet, as well as the access control lists (ACLs) that filter packets based on their header fields. The data plane also implements functions such as tunneling, queue management, and packet scheduling.

Control plane: The control plane consists of the network-wide distributed algorithms that

compute parts of the state in the data plane. The convergence times of these algorithms *vary from seconds to minutes*. For example, the control plane includes BGP update messages and the BGP decision process, as well as the Interior Gateway Protocol (such as OSPF), its link-state advertisements (LSAs), and the Dijkstra’s shortest-path algorithm. A primary job of the control plane is to compute routes between IP subnets, including combining information from each routing protocol’s Routing Information Base (RIB) to construct a single Forwarding Information Base (FIB) that drives packet forwarding decisions. Currently, the control plane exhibits the classic symptom of an over-engineered yet *unstable* system: the decision logic (e.g., for controlling reachability) is spread across multiple independently configured protocols or mechanisms and a local configuration error may cause cascading network-wide failures.

Management plane: The management plane stores and analyzes measurement data from the network and generates the configuration state on the individual routers. For example, the management plane collects and combines Simple Network Management Protocol (SNMP) statistics, traffic flow records, OSPF LSAs, and information extracted from BGP update message streams. A tool that configures the OSPF link weights and BGP policies to satisfy traffic engineering goals would be part of the management plane. Similarly, a system that analyzes traffic measurements to detect denial-of-service attacks and configures ACLs to block offending traffic would be part of the management plane.

From this view of the Internet architecture, the 4D architects have identified the following problem: The management plane is currently the only place where decisions are made based on *network-wide* information to meet *network-level* performance objectives, but placing these control functionalities in the management plane suffers from two fundamental weaknesses. First, the time scale of their operation is too long for them to adapt to changing network conditions without causing noticeable periods of severe performance degradation. Second, the management plane does not have direct control over the data plane, or more precisely, the FIB entries at the routers. The decisions made at the management plane have to be carried out through setting specific protocol parameters (e.g., OSPF weights) in the control plane. However, determining the right protocol parameters is often an NP-hard problem, requiring complex modeling and inverting of the actions of the control plane. Furthermore, this type of indirect control creates a performance bottleneck since it is not conducive to an integrated view of different mechanisms and joint optimization of multiple metrics. Rexford et al. (2004) and Greenberg et al. (2005c) provide several detailed examples of this problem.

The 4D architects argue that network-level decision making at a faster time scale and direct control are necessary to meet stringent QoS and security requirements.

Continuing on the current evolution path by tweaking the management and control planes will not fundamentally address either of the issues. A revolutionary change to the Internet architecture is inevitable.

THE 4D ARCHITECTURE

The design of the 4D architecture centers on streamlining network-level decision making and execution. Conceptually, network control, and management functions are refactored into four planes: Decision, Dissemination, Discovery, and Data; thus the name 4D. Before we delve into the role of each plane in the 4D architecture, we follow the main theme of this chapter by first presenting three design principles behind the refactoring of functions.

New Design Principles for Network Control

The 4D designers carefully researched the root causes of some of the major problems plaguing the current Internet architecture, to identify the desirable features for a new approach to network control (Rexford et al. 2004; Greenberg et al. 2005c). The problems examined included reachability control, traffic engineering, and planned maintenance. The effort has led to the formulation of the following design principles for crafting a more robust network architecture (Greenberg et al. 2005c).

Network-level objectives: *A network should be configured via specification of the requirements and goals for its performance, which should be expressed separately from the low-level network elements.*

Network-wide views: *Timely, accurate, network-wide views of topology, traffic, and events are crucial for running a robust network.*

Direct control: *Satisfying network-level objectives is much easier with direct control over the configuration of the data plane. The control and management system should have both the ability and the sole responsibility for setting all the state in the data plane that directs packet forwarding.*

Refactoring of Network Control and Management Functions

Guided by the design principles above, the 4D proposal refactors network control and management functions into four planes, as illustrated in Figure 4. Below is a brief description of the main functions of each plane (Greenberg et al. 2005b).

Decision plane: The decision plane makes *all* decisions driving network control, including reachability, load balancing, access control, security, and interface configuration. Replacing today's management plane, the decision plane operates in real time on a network-wide view of the topology (e.g., layer-3 topology, as well as layer-2 and layer-1 inventory), the traffic (e.g., the traffic matrix), and the capabilities and resource limitations of the routers. The decision plane directly configures the data plane based on network-level objectives, such as a reachability matrix, load-balancing goals, survivability requirements, and planned maintenance events. The algorithms in the

Figure 4: Four planes of 4D architecture with network level-objectives, network-wide views and direct control (Greenberg et al. 2005b)

decision plane may be customized based on knowledge of the network structure (e.g., simple path-computation algorithms for a ring topology). In one extreme design point, the decision plane may be a logically centralized component, with its functionality replicated by multiple decision elements (DEs) that connect directly to the network for fast, reliable communication with the routers and switches.

Dissemination plane: The dissemination plane provides a robust and efficient communication substrate that connects routers/switches with decision elements. Although control information may traverse the same set of physical links as the data packets, the dissemination paths are maintained separately from the data paths so they can be operational without requiring configuration or successful establishment of paths in the data plane. In contrast, in today's networks, control and management data are carried over the data paths, which need to be established by routing protocols before use. The dissemination plane moves management information created by the decision plane to the data plane and state identified by the discovery plane to the decision plane, but does not create state itself.

Discovery plane: The discovery plane is responsible for discovering the physical components in the network and creating logical identifiers to represent them. The discovery plane defines the scope and persistence of the identifiers, and carries out the automatic discovery and management of the relationships between them. This includes box-level discovery (e.g., what interfaces are on this router? How many FIB entries can it hold?), neighbor discovery (e.g., what other routers does this interface connect to?), and discovery of lower-layer link characteristics (e.g., what is the capacity of the interface?). The decision plane uses the information learned from the discovery plane to construct network-wide views. In contrast, in today's IP networks, the only automatic mechanism is neighbor discovery between two preconfigured and adjacent IP interfaces; physical device discovery and associations between entities are driven by configuration commands and external inventory databases.

Data plane: The data plane handles individual packets based on the state that is *output* by the decision plane.

This state includes the forwarding table, packet filters, link-scheduling weights, and queue-management parameters, as well as tunnels and network address translation mappings. The data plane may also have fine-grain support for collecting measurements on behalf of the discovery plane.

The results from an initial experimental study of the 4D architecture have confirmed the potential of the 4D design to achieve more robust and more efficient network-level decision making than currently possible (Greenberg et al. 2005c). The same study also shows that a logically centralized decision plane, with decision functions and state replicated across multiple DEs, is resilient in the event of link/router/DE failures or network partitions.

CONCLUSION

We have examined the Internet architecture from a historic perspective. Now it should be clear that the Internet is a success not purely because of economic forces; the network was built with a solid technology foundation which allows it to grow rapidly, foster innovations, and adapt to new application requirements. I hope you are also convinced that new thinking at the architecture level may be required in order to move forward and make the Internet become the integrated communications infrastructure of the future. This area of networking boasts a rich set of exciting research topics. For example, how to turn network configuration from an art, prone to human errors and cascading failures, into a science with precise abstractions and sound reasoning/checking frameworks (Maltz et al. 2004; Xie et al. 2005). A research agenda specific to the 4D architecture is outlined in Greenberg et al. (2005b).

ACKNOWLEDGMENT

I'd like to thank my colleagues Peter Denning and John Gibson for vetting early drafts of this writing and providing helpful feedback. I'd also like to thank five anonymous reviewers whose insights have led to significant improvements in both content and presentation.

GLOSSARY

Addressing: Means to uniquely identify source and destination of packets.

Data formatting: Means to convert application data into packets.

Firewall: Hardware device or software program which establishes a security perimeter around a network.

Forwarding: Means to move packets from input ports to output ports of a router.

Internet architecture: Communication services provided by the network, core building blocks for these services, and division of functionality among network elements.

IP: Internetworking protocol.

Network control and management: All functionality deployed for managing resources in the data plane.

Packet switching: Communication paradigm in which large messages are partitioned into multiple, self-contained packets.

Quality of service: Level of performance guarantee provided by a network, measured by packet delay, loss rate, throughput, etc.

Resource allocation: Techniques for dividing available network resources among traffic flows of different users.

Routing: Means to determine a suitable path from a given source to a given destination.

Service model: Abstraction of communication services provided by a network.

TCP: Transmission control protocol, which provides reliable service.

Traffic engineering: Optimization of resource allocation for a given traffic matrix.

Tunneling: Encapsulating a packet within another packet.

UDP: User datagram protocol.

Virtual private network: A private network where nodes are connected via encrypted tunnels built over the public Internet.

INTRODUCTION

It is difficult to imagine modern living without the Internet. It connects all kinds of computer systems from million dollar supercomputers to personal computers worth no more than a couple of hundred. The networks that connect them are varied, from wireless to wired, from copper to fiber. All of this is enabled by protocols and software collectively known as the *TCP/IP* suite or simply *TCP/IP*.

The two primary protocols in the suite are IP (Internet protocol) and TCP (transmission control protocol). IP delivers packets from machine to machine using Ethernet or other physical layers and routers. TCP, running on top of IP, reliably delivers packets from process to process. IP

requires the support of the infrastructure protocols. ARP (address resolution protocol) maps addresses of the physical layer to IP addresses. ICMP (Internet control message protocol) informs of errors and controls packet traffic. UDP (user datagram protocol) is a thin layer over IP serving those applications where throughput is more important, and unreliability issues are secondary. The size of the Internet is so large that routing tables must be constructed with the help of routing protocols such as RIP (routing information protocol) OSPF (open shortest path first) and BGP (border gateway protocol). Domain name system (DNS) brings not only mnemonics but also indirectly stabilizes the association of services to IP addresses.

TCP/IP details constitute one or more university courses on computer networks. Entire textbooks have been written on the topic that this chapter is attempting to cover. Different views exist as to what should be included under the heading of TCP/IP suite. Our goal is to present the practical TCP/IP landscape as it is today. To limit this chapter to some thirty pages in print requires that certain protocols are treated only briefly, and several other protocols are barely mentioned.

This chapter describes the core protocols known as IP, TCP, UDP; infrastructure protocols named ARP, ICMP, DHCP (dynamic host configuration protocol), SNMP (simple network management protocol), and DNS; application protocols such as, HTTP, SMTP (simple mail transfer protocol), POP (post office protocol), IMAP (Internet messaging access protocol), FTP (file transfer protocol), and SSH (secure socket shell); and the next generation of TCP/IP. As we describe these protocols, we will point out any weaknesses. The definitions of several terms are collected at the end in the glossary.

Protocols

A computer system communicates with another system by sending messages. The Internet is a packet-switched network; messages are split up into *packets*, which are logically viewed as sequences of fields. A *field* is a grouping of certain consecutive bytes or bits from the packet. Depending on the protocol, a packet is retermed as a frame, a datagram, or a segment.

The communication of messages is actually between a process running on one system and one running on the other system. Many of these processes are standard components of an operating system (OS); others are invoked when necessary as independent programs.

The rules of the protocol govern the communications between two or more processes, and their behavior in terms of semantics, timing, and ordering. The protocol also determines the data compression method, how the sender will indicate that it has finished sending, and so on. A protocol describes not only the syntax or structure of the message, that is, of the various fields of a packet, but also the interrelationships of the fields, the type of error checking to be used, and validity conditions.

RFCs

TCP/IP is an open system. Its protocols are written up as technical reports known as RFC (Request for Comments) documents and receive wide scrutiny. RFCs are freely downloadable public documents archived at www.rfc-editor.org. In general, these are proposed designs and solutions published by researchers from universities and corporations soliciting feedback. Protocols evolve through many drafts and versions. Some of these become Internet standards. The Internet Standards Process is described in RFC 2026. The status of various RFCs as standards is currently (2007) described in RFC 3700. In this chapter, we cite only the latest and/or the most relevant RFC for each protocol.

RFCs depict a packet as stacked rows of adjacent rectangles, with tick marks for bits. The field names are written inside the rectangles. When the row is too long to fit in the page width, the row is folded into several 32-bit wide rows, as shown in Figure 1. The indices of the bits start from 00 at the left to 31 at the right. The unit digits of these bit indices are shown in the second row, and the tens digits are shown in the first row. Indices of the bytes start from top-left at 0 but are not shown.

Implementation Issues

In general, there are multiple implementations of each protocol. They have become interoperable; this is often attributed to the fact that many of the implementations of the protocols are open source. However, their behaviors do differ in performance, resource usage, and in other details, often omitted in the RFCs, for example, in dealing with invalid packets. Security attacks have often exploited these details. Packets containing “unexpected” values in some of the fields are illegal in the sense that a legitimate sender would not have constructed them. Software/firmware in the receiver ought to check for such illegal packets, but legacy software was not cautious. Attackers have written special programs that construct illegal packets and cause the receiving network hosts to crash or hang. All major OSs have made improvements in their implementations of the protocols.

An attacker wants to identify the exact version of an OS running on a targeted victim. Nuances in the TCP/

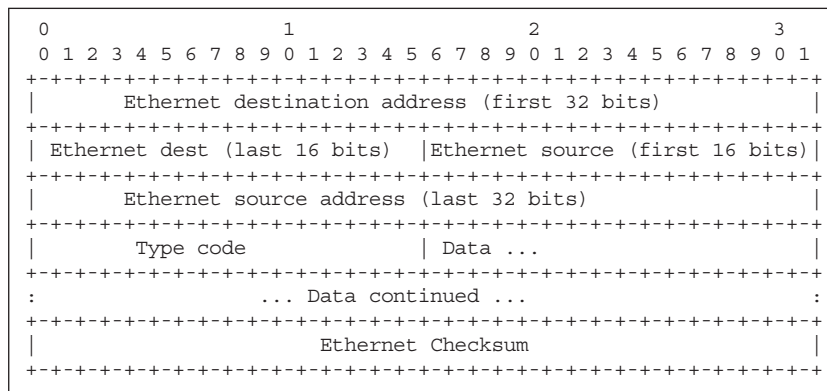

Figure 1: Ethernet (10- and 100 Mbps) frame

IP stacks implemented in the various OSs and versions of the same OS make it possible to remotely probe the victim host and identify the OS. Such probing deliberately constructs illegal packets, attempts to connect to each port, and observes the responses it gets.

A large number of TCP/IP server programs suffer from a class of programming errors known as buffer overflows. Many of these server programs run with the privileges of a superuser. Among the many servers that suffer from such bugs are several implementations of FTP servers, the ubiquitous DNS server program called `bind`, the popular mail server called `sendmail`, and the Web server IIS, to name a few. An attacker supplies cleverly constructed inputs to such programs causing them to transfer control to executable code he or she has supplied. A typical inputted “code” produces a shell that he can interact from a remote machine with all the privileges of the super user.

This chapter does not focus on vulnerabilities, but we do hint at the specifics of these issues. There are several chapters in this book that cover security issues, such as “Network Attacks,” “Intrusion Detection Systems,” “Virtual Private Networks,” “Cryptography,” “Authentication,” and “Password Authentication.”

LAYERS

Network protocols are easier to understand as a stack of layers, with each layer providing the functionality needed by the layer above it. In each layer, there are one or more protocols.

Encapsulation

The data unit of each layer is *encapsulated* by the layer below it (Figure 2), similarly to how sheets of paper are enclosed in an envelope. Each layer adds control information, typically prefixed to the data, before passing on to the lower layer. An application data unit [AP] is encapsulated by the TCP layer by computing a TCP header TCPH and

prefixing it as [TCPH [AP]]. The IP layer encapsulates it as [IPH [TCPH [AP]]], where IPH is the IP header. Ethernet encapsulates it as [EH [IPH [TCPH [AP]]] FSC], where EH is the Ethernet header, and FSC is a frame check sequence generated by the Ethernet hardware.

The layers are used in both directions: receiving and sending. While sending, each layer encapsulates the data payload supplied by the above layer. While receiving, each layer strips off the headers and suffixes of the layer to produce the data payload for the layer above it.

Connections

We will be characterizing protocols as either connection-oriented or connectionless.

In the connection-oriented communication, there are three well-defined phases: (i) connection establishment, (ii) data transfer, and (iii) connection release. A client A initiates the negotiation for a connection with B. Based on resource considerations and other issues, B may or may not agree to connect. If it does, it allocates the resources for this virtual circuit. The data transfer can now happen and must always contain a connection identifier. There may be gaps of idle time when there is no data transfer even though the connection is not broken. When A or B realizes that there is nothing more to communicate, the connection is closed, releasing all the resources allocated to it.

In the connectionless communication, one process sends data to another without prior negotiation. The recipient does not acknowledge the receipt of the message, but for communication to be successful, it should be ever ready to receive. The sender has no guarantee that the message is indeed delivered. In general, connectionless service will be faster and less resource consuming than a corresponding connection-oriented service but at a cost of no guarantee of delivery, order, or duplication. Long (in terms of time), steady, and large (in terms of content size) transfers benefit from virtual

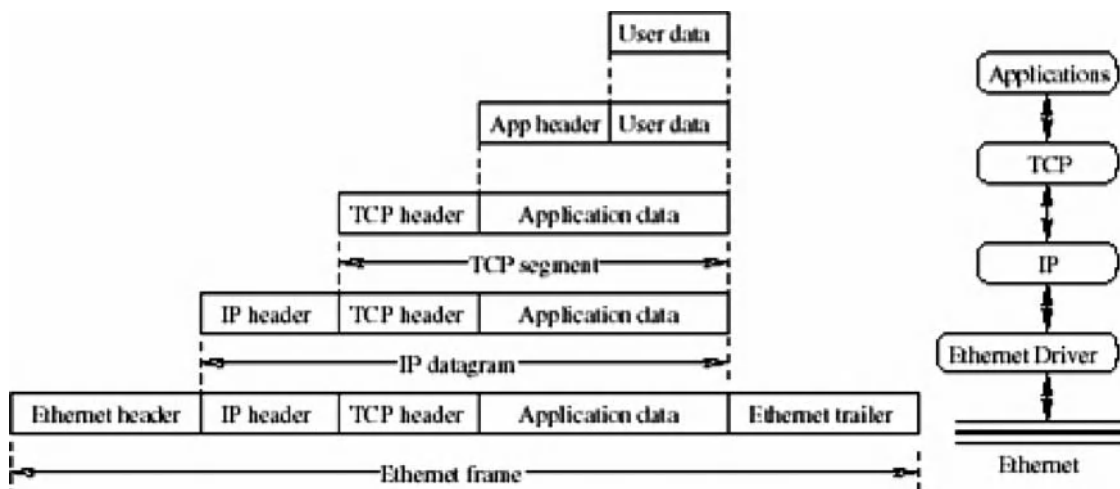

Figure 2: Encapsulations

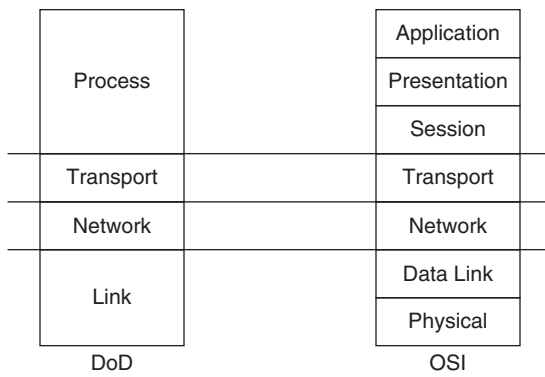

Figure 3: Comparison of DoD and OSI models

circuits. Infrequent and short transfers need only have the connectionless mode.

Models

There are three models of layers: the DoD (Department of Defense), the OSI (open system interconnection), and the “hourglass” models. All the models bring in the notion of layers based on overall functionality, not performance, resources, or even requirements. The DoD and OSI models are shown in Figure 3.

The DoD Model

This model is widely used but unofficially. It is referred to as (i) the TCP/IP model, (ii) the DoD (U.S. Department of Defense) model, or even more simply (iii) the Internet reference model. This model organizes networks into four layers. The location of various protocols in the layers is shown in Figure 4.

1. The *link* (or network access) layer deals with delivery over physical media. It defines the format of a data frame and physical addresses of the devices, and uses the physical and logical properties of the connection to transmit a frame.

2. The *network* (or Internet) layer deals with delivery between source and destination machines. The network layer accepts messages from the source host, converts them into packets of bytes, and sends them through the data link. This layer deals with how a route from the source to the destination is determined. This layer also deals with congestion control. IP, ARP (address resolution protocol), RARP (reverse ARP), ICMP (Internet control message protocol), RIP (routing information protocol), BGP (border gateway protocol), IGMP (Internet group management protocol), and so on belong to this layer.
3. The *transport* (or host-to-host) layer deals with connections, flow control, retransmission of lost data, and so on. TCP and UDP are in this layer.
4. The *application* (or process) layer deals with user-level services. This layer includes protocols such as SSH and SSL/TLS, in addition to those shown (FTP, HTTP, etc.) in Figure 4. This layer corresponds to the session, presentation and application layers of the OSI model (refer to Figure 3).

Note that in some literature, the DoD model is described as having five layers where the physical portion of the link layer is introduced as a separate layer at the bottom.

SCTP (stream control transmission protocol) is defined in RFC 2960 (2000), DCCP (datagram congestion control protocol) is defined in RFC 4340 (2006). Both are transport layer protocols. Both are on the IETF standards track. Because of space reasons and because these are yet to be deployed widely enough, we omit further discussion of these two protocols.

The OSI Model

The OSI (open systems interconnection) model of computer networks is officially recognized by the ISO (International Organization for Standardization). It has seven layers. The practical world of TCP/IP networking was in full use by the time the OSI model was formulated. The OSI model is influential for design purposes, but its

Figure 4: Protocol placement in the DoD model

protocols, developed alongside the OSI model, such as connectionless network protocol (CLNP), transport protocol class 0 (TP0), and common management information protocol (CMIP), are not widely deployed. We place the DoD protocols, rather than CLNP or TP0, as examples into the OSI seven layers. Note that some DoD protocols overlap multiple OSI layers.

1. The bottom most layer, known as the *physical layer*, provides the physical means of carrying the stream of bits. Ethernet, Wireless 802.11, T-carrier, and DSL (digital subscriber line) are examples of this layer. All media are considered functionally equivalent. The differences are in speed, convenience, and cost.
2. The *data link layer* structures the raw stream of bits of the physical layer and, using its encoding functionality, sends and receives a meaningful message unit called a *frame* and provides error detection functions. A frame includes checksum, source and destination addresses, and data. The frame boundaries are special patterns of bits. Software of this layer will retransmit a frame if it is damaged, for example, because of a burst of noise on the physical layer. This layer describes the specification of interface cards to specific types of networks (e.g., Ethernet, and token ring). The data link layer is divided into the media access control (MAC) sublayer, which controls how a computer on the network gains access to the data and permission to transmit it, and the logical link control (LLC) sublayer, which controls frame synchronization, flow control, and error checking. Example protocols from the TCP/IP suite that occupy this layer are SLIP (serial-line Internet protocol) and PPP (point-to-point protocol).
3. The *network layer* accepts messages from the source host, converts them into packets of bytes, and sends them through the data link. This layer deals with how a route from the source to the destination is determined. This layer also deals with congestion control. IP, ARP, RARP, ICMP, RIP, BGP, IGMP, and so on belong to this layer.
4. The *transport layer* transfers data and is responsible for host-to-host error recovery and flow control. TCP, SCTP, and UDP belong to this layer. UDP provides connectionless service, and TCP provides connection-oriented service (Iren et al. 1999).
5. The *session layer* establishes, manages, and terminates connections between the programs on the two hosts that are communicating. The concepts of ports and connections belong to this layer. SAP (session announcement protocol), NetBIOS, SDP (session description protocol), and so on belong to this layer.
6. The *presentation layer* provides independence from possibly different data representations, such as ASCII, little or big endian, MIDI, and MPEG. XDR (external data representation), SSL (secure sockets layer), TLS (transport-layer security), and so on belong to this layer.
7. The *application layer* supports the end-user invoked programs. HTTP, IMAP (Internet messaging access

Figure 5: The hourglass model

protocol), NTP (network time protocol), POP, FTP, telnet, rlogin (Remote Login), SMTP, SNMP, SOCKS, X-Window, NFS (network file system), Web services, and so on are part of this layer.

The OSI model is discussed in most textbooks because of its pedagogical utility but is considered obsolete.

The Hourglass Model

Internet protocols can be described as following an hourglass model with IP at the neck of the hourglass (Figure 5). The hourglass illustrates dependencies among the underlying networks, IP, and the applications.

PHYSICAL AND LINK LAYERS

A few prominent entries from the physical and link layers are described in this section.

Ethernet

Ethernet has been standardized by the Institute of Electrical and Electronics Engineers as IEEE 802.3. There are variations of Ethernet, and the plain Ethernet now refers to 10-megabits-per-second (Mbps) transmission speed, Fast Ethernet refers to 100 Mbps, Gigabit Ethernet refers to 1000 Mbps, and 10GbE refers to 10 Gbps. The connecting media varieties include twisted pair (1000Base-T, 100Base-T, with RJ45 connectors), thick coaxial system (10base5), thin coaxial (10base2), and fiber-optic systems (10basesF).

Ethernet Frames

A frame describes the structure of a byte sequence that constitutes one unit on the physical medium. Every Ethernet controller is assigned a worldwide unique 48-bit MAC address by the factory. For communication among humans, the MAC address is written with each byte in hexadecimal, separating bytes with either a hyphen or a colon, as in 00-0A-E6-9B-27-AE. Every Ethernet frame (refer to Figure 1) has a 14-byte header that begins with the 6-byte MAC addresses of the destination and source followed by a 2-byte-long type code. Ethernet can

support IP and other protocols simultaneously. The type code identifies the protocol family (such as IP, ARP, and NetBEUI). The different frame types have different formats and maximum transmission unit (MTU) values but can coexist on the same physical medium. The data field is from 46 to 1500 bytes in length. Following the data, there is a 4-byte checksum (see Glossary) frame check sequence (FCS) computed by the Ethernet controller for the entire frame.

There are several types of Ethernet frames:

- Ethernet Version 2 frame (refer to Figure 1) was described previously.
- The Raw IEEE 802.3 frame is almost identical to the Ethernet Version 2 frame, except that the 2-byte Type Code field is now interpreted as the length of the data. Because the assigned type codes are greater than 1500 while the data length is at most 1500, there is no ambiguity.
- The IEEE 802.2 LLC frame inserts into the raw frame three 1-byte LLC fields destination service access point (DSAP), a source service access point (SSAP), and a Control field between the Frame Length and Data.
- IEEE 802.2 LLC/SNAP frame sets DSAP to 0xAA, SSAP to 0xAA, and Control field to 0x03, and inserts a 5-byte sub network access protocol (SNAP) field before the Data begins.

All the preceding four frames begin with synchronizing bits, called the preamble, which repeats the bit string 10101010 seven times, and a start frame delimiter 10101011; however, these 8 bytes are not counted in the frame length. These were omitted in Figure 1.

Every Ethernet device is expected to listen for frames containing its MAC address as the destination. All devices also listen for Ethernet frames with a wildcard destination address of FF-FF-FF-FF-FF-FF, called a broadcast address. When a packet is received by the Ethernet network interface card (NIC), it computes the checksum and throws the packet away if an error is detected by the checksum. If the type code is IP, the Ethernet device driver passes the data portion of the frame up to the IP layer of the OS.

Under OS control, the NIC can be put into a so-called promiscuous state wherein the NIC listens to all frames regardless of their destinations.

Unswitched Networks

In an unswitched network, such as when each host is connected to a hub or the obsolete thin cabled Ethernet, every NIC can see the frame being sent. All hosts on the network contend equally for the transmission opportunity. Access to the shared medium is governed by the MAC mechanism based on the carrier sense multiple access with collision detection (CSMA/CD) system. To send data, a host waits for the channel to become idle and then transmits its frame. If two or more devices do try to transmit at the same time, after transmit collisions were detected c times so far, each device chooses a random integer n from 0 to 2^{k-1} , $k = \min(c, 10)$, and waits for a period equal to $n \cdot s$, where s is a time period based on

propagation delays, before trying to transmit again. This “exponential back off” ensures that access to the network channel is fair and that no single host can lock out other hosts.

Switched Networks

Switched networks use either twisted-pair or fiber-optic cabling, with separate conductors for sending and receiving data. Collision detection is not necessary because the station and the switch are the only devices that can access the medium. End stations and the switch can transmit at will, achieving a collision-free environment.

Unswitched Ethernet segments have all but disappeared. Switched Ethernet replaces the shared medium of legacy Ethernet with a dedicated segment for each host and extends the bandwidth. Today, a typical end user connects to a full duplex switched Ethernet, instead of hubs to connect individual hosts or segments. Note that a *hub* is a physical layer device. It transmits the frames received from one port to all other ports it has. A *switch* is a link layer device. A *switch* builds (“learns”) a table of ports and the MAC address it is connected to, reads the destination address of each frame, and forwards a frame it receives to only the port connected to the destination MAC address; the other ports do not see the frame.

Sniffing

Sniffing is eavesdropping on the network by a process, the sniffer, on a machine S that records copies of packets sent by machine A intended to be received by machine B. Such sniffing, strictly speaking, is not a TCP/IP problem, but it is enabled by the physical and data link layers. Sniffing can be used for monitoring the health of a network as well as capturing the passwords used in telnet, rlogin, and FTP connections.

In the normal mode, an NIC captures only those frames that match its own MAC address. In the promiscuous mode, an NIC captures all frames that pass by it. In an unswitched Ethernet segment, sniffing is therefore easy. The sniffer can be run on some other host in the same subnet as the victim. The volume of such frames makes it a real challenge for an attacker to either immediately process all such frames fast or clandestinely store them for later processing.

Switched Ethernet mitigates sniffing attacks. If the LAN segment is switched, a sniffer needs to be run either on the victim machine whose traffic is of interest, or on the router. However, switches can be “overwhelmed” into behaving as though they are hubs.

An attacker at large on the Internet has techniques that make it possible to remotely install a sniffer on the victim machine.

IEEE 802.11 a/b/g/n Wireless LANs

This section briefly describes wireless LANs known as the IEEE 802.11 family. For more detailed information, see Part 3 of this book. The 802.11a operates at a theoretical maximum speed of 54 Mbps, 802.11b at 11 Mbps, and 802.11g at 54 Mbps. Note that WiMAX (Worldwide Interoperability for Microwave Access, Inc.) is unrelated to 802.11.

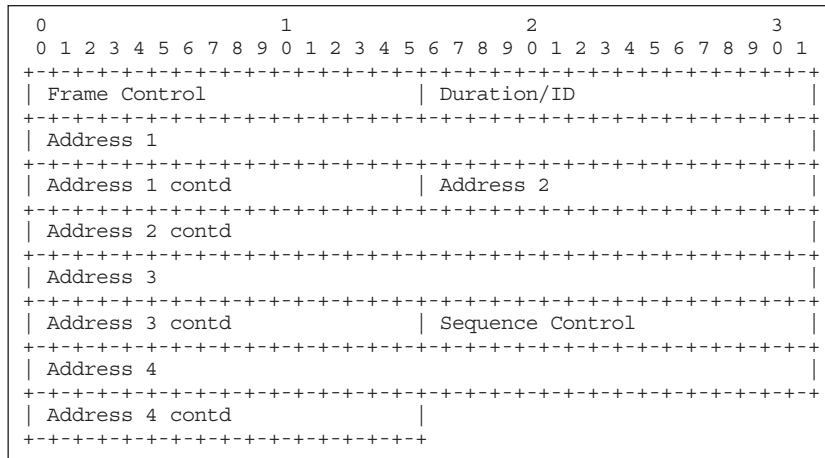

Figure 6: An IEEE 802.11 MAC header

Stations and Access Points

A wireless network *station* provides a radio link to another station. The station has a MAC address, a world-wide unique 48-bit number, assigned to it at the time of manufacture, just as wired network cards do. An *access point* (AP) is a station that provides frame distribution service to stations associated with it. Each AP has a 0- to 32-byte-long service set identifier (SSID) that is used to segment the airwaves for usage. The AP itself is typically connected by wire to a LAN.

Frames

A dot-11 frame consists of a MAC header (see Figure 6) followed by a frame body (payload) of 0 to 2312 bytes and an FCS.

There are three classes of frames. The *management* frames establish and maintain communications. The *control* frames help in the delivery of data. The *data* frames encapsulate the OSI network layer packets. These contain the source and destination MAC address, the BSSID (Basic Service Set Identifier), and the TCP/IP datagram.

Authentication and Association

Data can be exchanged between the station and AP only after a station is authenticated and associated with an AP. A station that is currently unauthenticated and unassociated listens for management frames known as *beacon* frames. The station and the AP mutually authenticate themselves by exchanging authentication management frames. After authentication, the station sends an association request frame, to which the AP responds with an association response frame that includes an association ID to the station. A station can be authenticated with several APs at the same time but associated with at most one AP at any time.

WEP and IEEE 802.11i

Wired equivalent privacy (WEP) is a shared-secret key system encrypting the payload part of the frames transmitted between an AP and a station. WEP is intended to protect wireless communication from eavesdropping and to prevent unauthorized access to a wireless network. Unfortunately, WEP is insecure.

Asynchronous Transfer Mode

Asynchronous transfer mode (ATM) is widely deployed as a backbone technology. ATM is connection-oriented. During the connection setup, the type of the flow, the quality of service (QoS), and so on are negotiated. A path between the end points and the needed resources to provide the QoS are allocated. Transfer of information is then begun. ATM uses fixed-length packets called *cells* for transport. Information is divided among these cells, transmitted, and then reassembled at their final destination. Each cell consists of a 48-byte payload and 5 bytes of additional information, referred to as overhead.

ATM itself consists of a series of layers. Its physical layer is based on various transmission media that range in speed from kilobits per second to gigabits per second. The layer known as the adaptation layer holds the bulk of the transmission converting between packets and cells. The ATM layer handles cell switching.

Frame Relay

Frame relay (FR) is a WAN (wide area network) protocol operating at the physical and data link layers. FR is less expensive but slower than ATM.

When a FR packet-switched network (PSN) is installed, several virtual circuits numbered with a data link connection identifier (DLCI) are established. A virtual circuit provides bidirectional communication between two stations. Virtual circuits may be permanent or switched. A switched virtual circuit is created for each data transfer and is terminated when the transfer is complete. A permanent virtual circuit is set up administratively by a network manager for a dedicated point-to-point connection and does not terminate when the transfer is complete.

Serial Line Internet Protocol

A serial network is a link between two computers over a serial line, which can be a dial-up connection over telephone lines or a direct connection between the serial ports of two computers. Serial line Internet protocol (SLIP; RFC 1055) defines the encapsulation protocol, just as an Ethernet frame envelops an IP packet. Unlike

Ethernet, SLIP supports only IP across a single link. The serial link is manually connected and configured, including the specification of the IP address. SLIP provides no mechanisms for address negotiation, error correction, or compression. However, many SLIP implementations record the states of TCP connections at each end of the link, and use header compression that reduces the size of the combined IP and TCP headers from 40 to 8 bytes.

Point-to-Point Protocol

Point-to-point protocol (PPP; RFC 1661, RFC 2153) replaces the older SLIP and is an encapsulating protocol for IP and other protocol datagrams over serial links. The encapsulation and framing adds 2-, 4-, or 8 bytes depending on the options chosen. PPP includes a link control protocol (LCP) that negotiates the encapsulation format, sizes of packets, authentication methods, and other configuration options. The CCP (compression control protocol) used by PPP negotiates encryption. The IP control protocol (IPCP) included in the PPP configures the IP address and enables the IP protocol on both ends of the point-to-point link.

Digital Subscriber Line

Digital subscriber line/loop (DSL) connects to the same wires as a regular telephone line via a DSL-modem that provides a higher-speed connection, than a typical modem does using either SLIP or PPP.

DSL creates 4.3125 kHz wide channels in the 10 kHz to 100 kHz bandwidth of the local loop, which is unused in plain old telephone service (POTS). The channels are then grouped into two: one for the upload bit stream and the other for the download bit stream.

There are many DSL technologies. Most homes have asymmetric DSL (ADSL) that divides up the available channels so that receiving speeds are much higher than sending speeds. An ATM layer can be built over the DSL. Early implementations of DSL used DHCP to provide network configuration details, where as current implementations often use PPP over Ethernet (PPPoE) or ATM (PPPoA).

INTERNET PROTOCOL

This section describes IP version 4 (RFC 791), which currently (2007) dominates the Internet. The next generation of TCP/IP, numbered v6, is described later.

IP delivers a sequence of bytes, called a *datagram*, from a source host S to a destination host D, even when the hosts are on different networks, geographically vastly separated. The IP layer forms an IP datagram from the byte sequence and the destination given by the upper layer during a send; the reverse of this happens during a receive.

The IP layer software discovers routes that the packet can take from S to various intermediate nodes, known as *routers*, ultimately arriving at D. Thus, IP is routable. Routing is described later in this chapter.

Each datagram travels independently, even when S wants to send several datagrams to D; each datagram is delivered independently of the previous ones.

The route that each packet takes may change. Thus, IP is connectionless.

The IP layer is designed deliberately not to concern itself with guaranteed delivery (e.g., datagrams may be lost or duplicated), but instead it is a “best effort” system. ICMP, described later, aids in this effort.

IP Addresses

An OS, during boot-up, assigns a unique 32-bit number known as its IP v4 address to each NIC located in the host system. There is no rigid relationship between the MAC address and the IP address. The IP address is obtained either by looking it up in a configuration file or via dynamic host configuration protocol (DHCP). When a machine is moved from one network to another, we must reassign an IP address that belongs to the new network. This is one of the problems that mobile IP solves.

IP addresses are typically written in a dotted-quad notation, such as *i.j.k.l*, where *i* is the first byte, *j* the second, *k* the third, and *l* the fourth byte. The first *p* bits constitute the network ID/address, and the rest $32 - p$ bits constitute the host ID. The number *p* is implicitly given by the IP address in the classful addressing scheme and identified externally in the classless scheme.

There are a few specific 32-bit numbers that are set aside for special usage. An IP address whose host ID portion is zero is the network address and is not the address of any host on that network. Occasionally, a network node X needs to discover certain information from other nodes, but the node X does not know the addresses of these others. In such situations, X broadcasts using special destination IP addresses. The direct broadcast address of X is the 32-bit number whose host ID portion is all ones and whose network address equals that of X. The limited broadcast address is 255.255.255.255.

Class A, B, and C Networks

Three address ranges known as class A, class B, and class C are of historical importance. In a class A address, the 0-th bit is always a 0, bits 1 through 7 identify the network, and bits 8 through 31 identify the host, permitting 2^{24} hosts on the network. In a class B address, the bit 0 is always a 1, bit 1 is always a 0, bits 2 through 15 identify the network, and bits 16 through 31 identify the host, permitting 2^{16} hosts on the network. In a class C address, bits 0 and 1 are both 1 always, bit 2 is a 0 always, bits 3 through 23 identify the network, and bits 24 through 31 identify the host, permitting 2^8 hosts on the network. This classful addressing is self-identifying in that the subnet ID and the host ID can be computed by examining the first two bits.

An organization would be assigned one or more blocks from these classes. Class C, with a maximum of 254 host addresses, is too small, whereas class B is too large to be densely populated, and the few class A networks are sparsely populated.

Subnets and Masks

A subnet is a collection of hosts whose IP addresses match in several bits indicated by the ones in a sequence of 32 bits known as a subnet mask, also written in the

dotted-quad notation. Thus, 255.255.255.0 is a mask of 24 ones followed by 8 zeroes. Because of this structure, the mask is also written as /24. Nodes and routers use the mask to identify the address of the network on which the specific host resides. The address of the network is the bitwise-AND of the IP address and the mask. The host ID is the bitwise-AND of the IP address and the complement of the mask.

CIDR and VLSM

The classless interdomain routing (CIDR) model (RFC 1518, 1993) solves the problems of efficient utilization of IP address space and reducing routing table sizes by using variable length subnet masking (VLSM). Instead of using class A, B, or C network identifiers of 8-, 16-, or 24 bits, CIDR replaces them with p bits, and the address is written as $a.b.c.d/p$. With CIDR, a single number $a.b.c.d$ can designate many different hosts based on the prefix.

A single network (say of class B) can be divided into finer ranges of addresses with different prefix values. Organizations can be assigned a smaller range instead of an entire class B. An organization can further divide it internally into sub subnets, and so on using VLSM.

A CIDR block is a collection of addresses that have the same prefix. It is possible that these are collections of networks belonging to different organizations, and the collection is then called a supernet. Modern routing protocols reduce their table sizes by constructing large CIDR blocks through prefix aggregation and maintaining a single row per block.

Public and Private Address Ranges

The public IP addresses are carefully controlled worldwide. The IANA, Internet Assigned Numbers Authority (www.iana.org), assigns the public IP addresses to organizations and individuals upon application.

There are three blocks of the IP address space intended for private intranets: (i) 10.0.0.0 to 10.255.255.255 (10/8 prefix, class A), (ii) 172.16.0.0 to 172.31.255.255 (172.16/12 prefix), and (iii) 192.168.0.0 to 192.168.255.255 (192.168/16 prefix, class C).

Most operating systems are internally structured to depend on the presence of a network layer. To facilitate this, the address 127.0.0.1 is assigned as the address of the `localhost` (spelled as one word) and 127.0.0.0 as the `localnetwork` (spelled as one word). Packets sent to this address do not actually travel onto the external network. They simply appear as received on the local (artificial) device.

That is, on the Internet at large, there must only be IP packets whose source or destination addresses are assigned public addresses.

IP Header

An IP header is a sequence of bytes that the IP layer software prefixes to the data it receives from the higher layers. The resulting IP header plus the data (see Figure 7) is given to the lower layer (e.g., the Ethernet card device driver). Except for the IP Options field, all other fields are fixed in length as shown. Minimally (i.e., without options), the IP header is 20 bytes in length. With IP options, an IP header can be as long as 60 bytes. The maximum length of an IP datagram is 65535 bytes. (IP over Ethernet limits this to 1500.)

IPv is the version number of the protocol, which is currently 4. The value of IHL multiplied by 4 is the length of the IP header in bytes. The type of service field specifies the “relative urgency” or importance of the packet. Total length is a 2-byte field giving the length, in bytes, of the entire packet, including the header, options (if any), and the packet data. The identification field, flags, and fragment offset are used to keep track of the pieces when a datagram must be split up as it travels from one router to the next. IP fragmentation is discussed further next. The time to live (TTL) is a number that is decremented by 1 whenever the datagram passes through a router node. When it goes to 0, the datagram is discarded, and an error message is sent back to the source of this packet. The protocol field identifies the protocol of the data area. The header checksum field is a 1’s complement arithmetic sum of the entire header viewed as a sequence of 16-bit integers. The source address is the datagram’s sender IP address, and destination address is the IP address of the intended recipient.

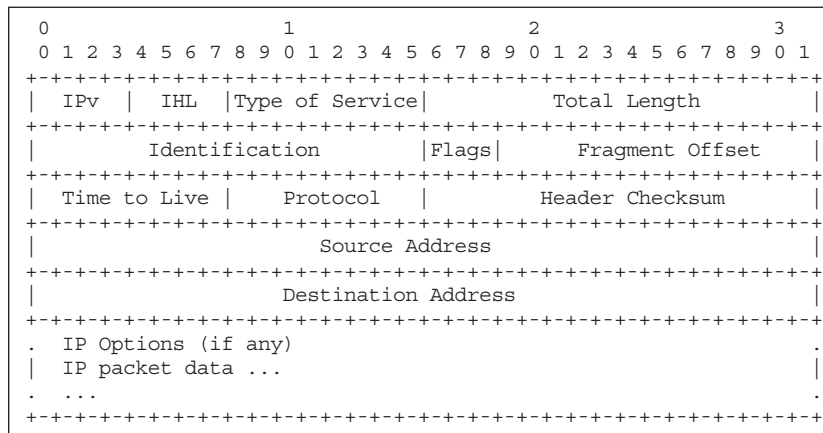

Figure 7: IPv4 datagram

IP Fragments

When datagrams are too large to be sent in a single IP packet, they are split up by an intermediate router unless prohibited by the Don't Fragment flag. IP fragmentation occurs when a router receives a packet larger than the maximum transmission unit (MTU) of the next network segment, usually determined by interface hardware limitations. All such fragments will have the same identification field value (refer to Figure 7). The fragment offset indicates the position of the current fragment in the context of the presplit-up packet. Intermediate routers are not expected to reassemble the fragments. The final destination will reassemble all the fragments into one IP datagram.

Mobile IP

As a mobile network host moves, its point of attachment may change, and yet to maintain existing transport-layer connections, it must keep its IP address the same.

The mobile node uses two IP addresses. The home address is static and is used to identify TCP connections. The care-of address changes at each new point of attachment. Whenever the mobile node moves, it registers its new care-of address with its home agent. The home agent redirects the packets to the current care-of address by constructing a new IP header that contains the care-of address as the destination IP address. This new header encapsulates the original packet, causing the home address to have no effect on the routing of the encapsulated packet until it arrives at the care-of address. When the packet arrives at the care-of address, the effect of this "tunneling" is reversed so that the packet once again appears to have the home address as the destination IP address. Mobile IP discovery of the care-of address uses an existing standard protocol called *router advertisement* (RFC 1256). A router advertisement carries information about default routers, and in addition carries further information about one or more care-of addresses. Home agents and care-of agents typically broadcast these advertisements at regular intervals (say, once every few seconds). A mobile node that needs a care-of address will multicast a router solicitation. An advertisement also informs the mobile node whether the agent is a home agent, a care-of agent, or both, and therefore whether it is on its home network or on a care-of network and about special features provided by care-of agents (for example, alternative encapsulation techniques).

The registration of the new care-of address begins when the mobile node, possibly with the assistance of the care-of agent, sends a registration request to the home address. The home agent typically updates its routing table. Registration requests contain parameters and flags that characterize the tunnel through which the home agent will deliver packets to the care-of address. The triplet of the home address, care-of address, and registration lifetime is called a binding for the mobile node. The home agent authenticates that the registration was originated by the mobile node.

Occasionally, a mobile node cannot contact its home agent. The mobile node tries to register with another home agent by using a directed broadcast IP address

instead of the home agent's IP address as the target for the registration request.

Each mobile node and home agent compute an unforgeable digital signature using one-way hash algorithm MD5 (Message Digest 5; RFC 1321) with 128-bit keys on the registration message, which includes either a time stamp or a random number carefully generated.

IP Issues

Several aspects of IP design have become troubling issues as the mischievous elements began to use the Internet.

The typical IP layer of an OS does not check for anomalies in the header. For example, an IP packet should not have source address and port equaling the destination address and port. The 1997 attack tool called *land* exploited this vulnerability.

Covert channels can be set up using the ID field of IP packets, IP checksums, and so on (Rowland 1997).

IP Spoofing

The IP layer of the typical OS simply trusts that the IP source address is valid. It assumes that the packet it received was sent by the host officially assigned to that source address.

Replacing the true IP address of the sender (or, in rare cases, the destination) with a different address is known as *IP spoofing*. Because the IP layer of the OS normally adds these IP addresses to a data packet, a spoofer must circumvent the IP layer and talk directly to the raw network device. IP spoofing is used as a technique aiding an exploit on the target machine. Note that the attacker's machine cannot simply be assigned the IP address of another host T using `ifconfig` or a similar configuration tool. Other hosts, as well as T, will discover (through ARP, for example) that there are two machines with the same IP address.

IP spoofing is an integral part of many attacks. For example, an attacker can silence a host A from sending further packets to B by sending a spoofed packet announcing a window size of zero to A as though it originated from B.

IP Fragment Attacks

A well-behaving set of IP fragments is non overlapping. Malicious fragmentation involves fragments that have illegal offsets. For example, the fragments may be so crafted that the receiving host in its attempts to reassemble calculates a negative length for the second fragment. This value is passed to a function (such as `memcpy`) that copies from/to memory, which takes the negative number to be an enormous unsigned (positive) number. A pair of carefully crafted but malformed IP packets thus causes a server to "panic" and crash. The 1997 attack tool called *teardrop* exploited this vulnerability. The 2004 *Rose Attack* sent two small IP fragments of 32 bytes each, from a SYN segment, that do not form a complete packet. The first fragment was with zero-offset, and the second fragment was set to an offset of 64800 bytes into the datagram.

The RFCs require no intermediate router to reassemble fragmented packets. Obviously, the destination must reassemble. Many firewalls do not perform packet

reassembly in the interest of efficiency. These only consider the fields of individual fragments. Attackers create artificially fragmented packets to fool such firewalls. In a so-called tiny fragment attack, two fragments are created where the first one is so small that it does not even include the destination port number. The second fragment contains the remainder of the TCP header, including the port number. A variation of this is to construct the second fragment packet with an offset value less than the length of the data in the first fragment so that upon packet reassembly, it overrides several bytes of the first fragment (e.g., if the first fragment was 24 bytes long, the second fragment may claim to have an offset of 20). Upon reassembly, the data in the second fragment overwrites the last 4 bytes of the data from the first fragment. If these were fragments of a TCP segment, the first fragment would contain the TCP destination port number, which is overwritten by the second fragment. Such techniques do not cause a crash or hang of a targeted system but can be used to bypass simple filtering done by some firewalls.

Fragmentation attacks are preventable. Unfortunately, in the IP layer implementations of nearly all OSs, there were/are bugs and naïve assumptions in the reassembly code.

ICMP

Internet control message protocol (RFC 792, 1981; RFC 950, 1985) is a required protocol that manages and controls the IP layer. In general, much of the best effort in delivering IP datagrams is associated with ICMP. The purpose of the ICMP messages is to provide feedback and suggestions about problems. The popular network utilities ping and traceroute use ICMP.

ICMP is in the network layer. But, an ICMP message is encapsulated as an IP datagram. These are treated like any other IP datagrams.

Message Format

Each ICMP message begins with a 1-byte ICMP type field, which determines the format of the remaining data, a one-byte code field, and a 2-byte checksum (Figure 8). ICMP messages are either error or query/reply messages.

Error Messages

ICMP is designed to report network errors, such as a host or entire portion of the network being unreachable or a packet being directed at a closed port. Error messages are reported to the original source on problems encountered

by a router or the destination host in processing an IP datagram. However, ICMP is not designed to correct errors. To avoid infinite regress, no ICMP messages are sent about ICMP messages. Also ICMP messages are not sent about errors in handling (i) other than fragment zero of fragmented datagrams, (ii) multicast address, and (iii) addresses such as 127.0.0.0, or 0.0.0.0.

In an ICMP error message, the 4 bytes of Rest of Header is set to 0, and the data section is the first 8 bytes of the IP datagram causing the error.

A Destination Unreachable (Type = 3) error message is sent to the original source host when a datagram cannot reach its destination. The code field indicates the cause.

A Source Quench Message (Type = 4) is sent (i) if the gateway does not have the buffering capacity to forward a datagram, or (ii) if datagrams arrive too fast to be processed.

A router R1 sends a Redirect Message (Type = 5) to a source host S if datagrams to a destination D through R1 will make the next hop to another router R2 and S can send directly to router R2.

The Time-Exceeded (Type = 11) ICMP error messages are delivered when the TTL of a datagram is 0. The traceroute utility constructs IP datagrams with well-chosen TTL values and collects the time exceeded messages to map a route from the source to a destination IP address.

The Parameter Problem (Type = 12) message is sent if a router finds a problem with any of the parameters in an IP header that causes it to drop the datagram.

Request/Reply Messages

The Echo Request (Type = 8) and Echo Reply (Type = 0) query messages can identify network problems. The well-known ping (packet Internet groper) command sends several echo requests, captures their echo replies, and displays statistics about speed and datagram loss.

The Router Advertisement (Type = 9) and Router Solicitation (Type = 10) messages are periodically multicast by a router announcing its multicast addresses. Hosts can discover the addresses of their neighboring routers simply by listening to the advertisements. When a host starts up, it may multicast a Router Solicitation to ask for immediate advertisements, rather than waiting for the next periodic ones to arrive. Note that these router discovery messages do not indicate which router is best to reach a particular destination. A host choosing a poor first-hop router for a particular destination should receive an ICMP Redirect from that router.

Figure 8: ICMP packet

A Timestamp Request (Type = 13) includes the time stamp, a 32-bit unsigned integer counting milliseconds since midnight UT, of the sender. A Timestamp Reply (Type = 14) Message includes the originate time stamp and the time stamp of the receiver. These can be used to estimate the round-trip time of a datagram or to synchronize clocks.

The Address Mask Request (Type = 17) and Address Mask Reply (Type = 18) messages enable a host to discover its address mask.

ICMP Issues

ICMP has been one of the easiest among the protocols to exploit. For example, the ICMP redirect message, intended to improve routing performance, has often been used maliciously.

ICMP scanning is a way to gather information regarding hosts on the Net (Arkin 2001). In the simplest form, Echo Request messages are sent, and the received Echo Replies are analyzed. The standard utility called ping does this with a single host. An attacker, however, uses a broadcast address and/or parallel sweeps.

The attack tool of 1997, called *smurf*, sends ICMP Echo Request messages. There are three hosts in smurfing: the attacker, the intermediary router, and the victim. The attacker sends to an intermediary an echo request packet with the IP broadcast address of the intermediary's network as the destination. The source address is spoofed by the attacker to be that of the intended victim. The intermediary puts it out on that network. Each machine on that network will send an echo reply packet to the source address. The victim is subjected to network congestion that could potentially make it unusable.

The so-called Ping of Death attack of 1996 sent an echo request packet that was larger than the maximum permissible length ($2^{16} - 1$).

ICMP echo request packets should have an 8-byte header and a 56-byte payload. ICMP echo requests should not be carrying any data. However, significantly larger ICMP packets can be generated carrying covert data in their payloads.

In addition to the exploits described here, ICMP has enabled several other exploits via reconnaissance and scanning.

USER DATAGRAM PROTOCOL

UDP (RFC 768, 1980) is a connectionless protocol belonging to the transport layer (OSI layer 4). It is a thin protocol on top of IP, providing high speed but low

functionality. UDP does not guarantee the delivery of datagrams. Messages can be delivered out of order, delayed, or even lost. Datagrams may get duplicated without being detected. The UDP protocol is used mostly by application services where squeezing the best performance out of existing IP networks is necessary, such as Trivial File Transfer (TFTP), NFS, and DNS.

Port Numbers

IP delivers host-to-host. Port numbers are used by the transport layer to multiplex communication between several pairs of processes. To each message, this layer adds addresses, called port numbers. The port numbers are assigned by the OS. The UDP layer of an OS picks up the IP datagrams, examines the UDP payload, extracts the destination port number, and delivers the UDP data to the process that registered with the destination port.

The port numbers appearing in the UDP header are similar to the TCP port numbers (see next section), but the OS support required by UDP ports is much simpler and less resource consuming than that of TCP ports.

The ports 0 to 1023 are reserved for specific well-known services provided by privileged processes. These numbers are assigned by IANA. These are often called *well-known* ports. For example, HTTP officially uses port 80, telnet officially uses port 23, and DNS officially uses port 53. The ports in the range 1024 to 49151 are called *registered ports* because they are listed by the IANA for specific services, but on most systems, these ports can be used by unprivileged processes. The *dynamic* or *private* ports range from 49152 to 65535. Client processes and nonstandard services are assigned port numbers by the OS at run-time. On most computer systems, there is a list of these port numbers and service names in a file named *etc/services*. Almost always, the same port assignments are used with both UDP and TCP.

User Datagrams

UDP packets are called user datagrams. The source port is the port of the sending process (Figure 9). When not meaningful, this field is set to 0. The destination port is the UDP port on the receiving machine, whose IP address is supplied by the IP layer. Length is the number of bytes in the datagram, including the UDP header and the data. Checksum is the 16-bit 1 complement of the 1 complement sum of the UDP header, the source and destination IP addresses obtained from the IP header, and the data, padded with 0 bytes at the end (if necessary) to make a multiple of 2 bytes.

Figure 9: UDP packet

is in use at any moment. Operating systems implement such buffers as cyclic buffers.

The TCP subsystem of the OS keeps track of the connection (that is, messages between the two processes of A and B) through SEQN and ACKN. TCP is full duplex; that is, A and B can send and receive segments at the same time. While continuing to send segments, A expects to receive segments from B that contain acknowledgement of its segments. This applies to B also. For compactness, the rest of this section is written from the perspective of one end of the connection at host A.

Acknowledgments are piggybacked on reply data. Each segment sent by B contains (i) the data payload that B wants to send to A, (ii) the SEQN of this payload, and (iii) the ACKN set equal to the *sequence* number of the next byte expected from A. Additionally, ACKN confirms to A that B has received all bytes numbered from ISN of A up to and including ACKN - 1. Obviously, the very first segment from A to B, and vice versa, do not have a valid ACKN, and hence ACK = 0.

TCP has a number of control bit flags that have, when set to 1, the following meanings: Urgent pointer is valid when URG is 1. Its value is an offset from the sequence number in this segment. ACK, acknowledgment number is valid; PSH, push function is active; RST reset the connection; SYN synchronize sequence numbers; and FIN, sender is finished with this connection. In a typical segment, we expect only ACK = 1 and all others to be 0.

TCP is a *sliding window* protocol that performs the following repetitively. TCP at A computes the data payload size for the segment, which is the lesser of (i) available number of bytes and (ii) the receive buffer window size of B. If this is zero, it pauses. Otherwise, it sends a segment to B made of consecutive bytes starting from the index of the next byte to be sent, SWNX. The SEQN in the segment is set to ISN + SWNX. SWNX is incremented by the length of this data payload for the next segment. All

the bytes of the send buffer to the left of SWLE have been acknowledged by B as successfully received. The number of available bytes to send is SWRE-SWNX. The window slides forward (i.e., both SWLE and SWRE are incremented by the same amount) as and when appropriate acknowledgements are received by A. SWRE is further considered in the sections on flow and congestion control. Note that the send buffer is filled by the local (i.e., at host A) process at its right edge.

A segment S received from B may or may not fall in the receive window of A as determined by the SEQN and segment length of S. The receive window is filled by the segments that do fall in this window. In between such filled sequences, there may be gaps because the corresponding segments are yet to be received. RWLE is moved to the beginning of the left most gap in the window. Note that TCP at A advertises the receive window size (RBRE - RWLE) in each segment it sends to B. The bytes between RBLE and RWLE-1 are for the local process, and as it consumes, RBLE byte index gets incremented. If RBLE = RWLE, the local process must pause.

State Diagram

A TCP server process starts its life by passively opening a port and listening to connection attempts from clients. This process causes a number of changes in the TCB data structures maintained by the TCP layer software. These transitions are described in a simplified manner by the state diagram shown in Figure 11. The boxes denote the states, and the arrows denote a state transition. Each transition has a label of the form input/output, which describes that while in the state U at the tail end of the arrow, if the event described by input occurs, the event described by output is caused, and a state transition to V occurs. We describe how to read this diagram further in the next few sections.

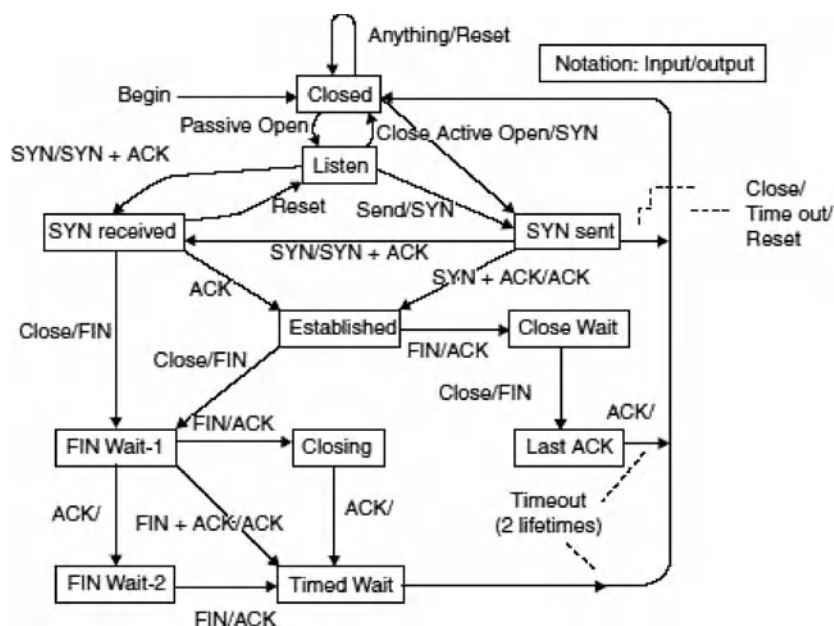

Figure 11: TCP state diagram

Connections

TCP establishes a connection (using the three-way handshake) between a client, say A, and a server, say B, transfers a continuous stream of bytes in each direction by packaging some number of bytes into segments, and in the end formally terminates (using the four-way handshake) the connection.

Establishment: Three-Way Handshake

A three-way handshake establishes a connection as follows:

- A: “I would like to talk to you, B.” A sends to B a segment with $ACK = 0$, $SYN = 1$, and ISN chosen by A. This segment includes an initial window size advertisement. A was in the Listen state and now enters SYN-sent state. B was in the Listen state and on receiving this SYN-segment, enters the SYN-received state.
- B: “OK, let’s talk.” B replies with a $SYN+ACK$ segment (i.e., $SYN = 1$ with $SEQN$ to the ISN of B, and $ACK = 1$, $ACKN = ISN$ of A + 1). At this point, B remains in the SYN-received state. The condition of the connection is known as *half-open*. If B was unwilling to talk, it would have responded with a $RST = 1$ segment refusing the request for service and would have moved into the Listen state.
- A: “Thanks for agreeing!” Having received the $SYN+ACK$ segment from B, A sends a segment with $ACK = 1$, $ACKN = ISN$ of B + 1, $SYN = 0$, $SEQN =$ previous $SEQN + 1$. At this point, A is in the Established state. When B receives this segment, B also enters the Established state, and the connection is fully open and functional: A and B can continue to exchange messages. In these messages, $ACK = 1$ and $SYN = 0$.

The ISN can be a zero, but that is not secure, so the ISN is randomly chosen.

Here is an example (shown in Figure 12 as a ladder diagram and with the ACK numbers in Table 1) where the client is on port 1037 establishing a connection with a service on port 80.

The connection establishment results in the creation of the TCP data structures at both ends.

Closing: Four-Way Handshake

This gracefully terminates a previously established connection between A and B as follows:

- A: “No more data from me.” A sends to B a segment with $FIN = 1$ and of course $ACK = 1$. The FIN flag is used when closing a connection down the normal way.

Figure 12: Three-way handshake steps in time

Host A enters the FIN-Wait-1 state. The receiving host B enters the CLOSE WAIT state and starts the procedure of gracefully closing the connection. Each end of the connection sends a segment with the $FIN = 1$. The receiver is expected to acknowledge a received FIN segment by sending a $FIN = 1$ segment.

- B: “I acknowledge your FIN .” B sends to A a segment with $FIN = 0$, $ACK = 1$, acknowledgment number = sequence number of A’s FIN segment + 1. On receiving the ACK segment from B, host A enters the FIN-WAIT2 state.
- B: “No more data from me either.” B sends to host A another segment but now with $FIN = 1$. B enters the Last-ACK state, and after two time-out periods, enters the CLOSED state.
- A: “I acknowledge your FIN too.” On receiving the FIN segment from B, host A sends to B a segment with $FIN = 0$ and $ACK = 1$. Host A enters the TIMED-WAIT state, and after two time-out periods, enters the CLOSED state.

So, four segments are used to close a TCP connection in the normal situation. This is a teardown of two *half-closes*.

From the state diagram, it can be seen that the FIN and ACK packets from B can arrive in the reverse order to the preceding or even $FIN+ACK$ together in one packet.

The preceding can be termed a graceful termination. There are two other ways that TCP connections terminate; see the section on “Connection Closing.”

TCP data structures at both ends are deleted upon closing a connection.

Timers

TCP depends on many timers that the host must maintain per (attempted) connection as it follows the state diagram (refer to Figure 11).

Table 1: An Example Three-Way Handshake

Step	SYN	ACK	Source Port	Destination Port	Sequence number	Acknowledgement number
a	1	0	1037	80	102723769	0
b	1	1	80	1037	1527857206	102723770
c	0	1	1037	80	102723770	1527857207

1. The Connection Establishment Timer is started on receiving the first packet of the three-way handshake. A typical value of this timer is 75 seconds. If a time-out occurs, the connection is aborted.
2. A Retransmission Timer is started when a segment is sent. Its value, known as RTO (retransmission time-out), is dynamically computed (RFC 2988). If the timer expires before an ACK is received, the segment is resent, and the timer is restarted.
3. A Delayed-Acknowledgement Timer is set when data are received that do not need to be acknowledged immediately. If, after 200ms, the acknowledgement is still pending (i.e., it has been unable to piggy-back on an outgoing data segment), it is then sent.
4. The KEEP-ALIVE Timer lets us distinguish silences caused because there is no data to send from those caused by a broken connection. Setting a KEEP-ALIVE timer allows TCP to periodically probe the other end. The default value of this timer is 2 hours. After the expiration of the timer, probes are sent to the remote end. The connection is dropped if the remote does not respond.
5. A FIN-WAIT Timer is started when there is a transition from the FIN-WAIT-1 state to the FIN-WAIT-2 state. The initial value of this timer is 10 minutes. If a packet with FIN = 1 is received, the timer is canceled. On expiration of the 10 minutes, the timer is restarted with a value of 75 seconds. The connection is dropped if no FIN packet arrives within this period.
6. TIMED-WAIT Timer is started when the connection enters the TIMED-WAIT state. This is to allow all the segments in transit to be removed from the network. The value of the timer is usually set to 2 minutes. On expiration of the timer, the connection is terminated.
7. A Persistence Timer is used to detect if any window size updates were lost. The timer is set when the remote node advertises a window size of zero, thus preventing any data being sent. If the window has not been opened when the timer expires, 1 byte is sent in case the window update was lost.

Flow Control

Flow control prevents the sending process from overwhelming the receiving process. The size of the sliding window is dynamically adjusted because of flow or congestion issues. Each acknowledgment segment from B to A advertises *rwnd* (Window Size field of Figure 10), which is the number of bytes B has in its receiver buffer. If *rwnd* is larger than the current sliding window size, TCP at A can increase it by incrementing the right edge of the window, SWRE. If it is smaller, let $Z = \text{SWRE} - \text{rwnd}$, and there are two cases. If $\text{SWNX} > Z$, set SWRE to SWNX and pause; else, set SWRE to Z and keep sending.

Congestion Control

Congestion is a condition of significant delay caused by overload of datagrams at one or more routers. A congestion window size *cwnd* that limits the number of

outstanding unacknowledged bytes that are allowed at any time is dynamically computed by the sender based on network congestion. The TCP sliding window size is the smaller of *rwnd* and *cwnd*. TCP improves throughput by avoiding congestion. When a segment loss is detected, TCP assumes that the loss is due to congestion. There are many variations on how *cwnd* should be adjusted.

TCP Slow-Start algorithm doubles *cwnd* until a slow-start threshold is reached. Then *cwnd* is increased by 1. When ACKs are not received, the slow-start threshold is set to half of *cwnd*, and the algorithm restarts.

TCP congestion control operates on two time scales. On round trip times (RTT) of the order of 10 to 100s of msec, TCP performs additive-increase, multiplicative-decrease (AIMD) control. At times of severe congestion, TCP operates on longer time scales of RTO. In an attempt to avoid congestion collapse, flows reduce their congestion window to one packet and wait for a period of RTO after which the packet is resent. Upon further loss, RTO doubles with each subsequent time-out. If a packet is successfully received, TCP reenters AIMD via slow start.

TCP congestion control has undergone major improvements in recent years resulting in many TCP variants that are soon to be adopted in actual implementations. For example, Linux 2.6 has TCP BIC and TCP CUBIC, and Windows Vista has TCP New Reno and Compound TCP.

Reliable Transmission

Recovery from data that is damaged, lost, duplicated, or delivered out of order is achieved using error control. Damage is handled by adding a checksum to each segment transmitted, checking it at the receiver, and discarding damaged segments. If the sender S does not receive an acknowledgment from the destination D within the RTO period, S retransmits the segment. The time-out period is continually adapted by TCP per connection by measuring the round-trip delay. At the receiver, the sequence numbers are used to correctly order segments that may be received out of order and to eliminate duplicates.

TCP Issues

This section briefly describes several TCP weaknesses. TCP has been in long and heavy use. Many of its implementations have made improvements that go beyond the prescriptions of its RFC. Nevertheless, there are several old issues with no clear solutions and new vulnerabilities are being discovered. For example, not all the control flags can be independently set or reset. The combinations of SYN FIN, SYN FIN PSH, SYN FIN RST, and SYN FIN RST PSH set to 1 are all illegal. Past implementations have accounted only for valid combinations, ignoring the invalid combinations as “will not happen.” Covert channels can be set up using the TCP initial sequence numbers, and so on. The TCP time stamps option can allow malicious, off-path third parties to stall systems with persistent TCP connections. For example, CERT advisory VU#637934 (2005) notes that some TCP implementations may allow a remote attacker to arbitrarily modify host time stamp values, leading to a denial-of-service condition.

Sequence Number Prediction

TCP exploits are typically based on IP spoofing and sequence number prediction. In establishing a TCP connection, both the server and the client generate an initial sequence number (ISN) from which they will start counting the segments transmitted. Host Y accepts the segments from X only when correct SEQ/ACK numbers are used.

The ISN is (should be) generated at random and should be hard to predict. However, some implementations of the TCP/IP protocol make it rather easy to predict this sequence number. The attacker either sniffs the current SEQ+ACK of the connection or can algorithmically predict them.

Even when random numbers are used, there have been problems. CERT VU#498440 (2001) notes that using random increments to constantly increase TCP ISN values over time provides insufficient variance in the range of likely ISN values, allowing an attacker to exploit the statistical weakness to predict the ISN and disrupt or hijack existing TCP connections or spoof future connections. A related weakness in BGP is described in the section on "Route Spoofing."

Connection Closing

The four-way handshake described previously is not the only way to close a connection. Connections can be closed by sending a TCP segment with its RST flag set to 1, which indicates to the receiver that a reset should occur. The receiving host accepts the RST packet, provided the sequence number is correct, and enters the CLOSED state and frees any resource associated with this instance of the connection. The RST segment is not acknowledged. A host B sends a connection resetting the RST segment if host A requested a connection to a non-existent port p on host B, or for whatever reason (idle for a long time, or an abnormal condition, etc.), the host B (client or the sever) want to close the connection. Resetting is unilateral. Any new incoming segments for that connection will be dropped.

The 2004 TCP reset attack led to severe concerns in the routing protocol BGP used in large routers. TCP (RFC 793) requires that sequence numbers are checked against the window size before accepting data or control flags as valid. It also specifies that RST control flags should be processed immediately, without waiting for out-sequence packets to arrive. Even though RFC 793 allows a TCP implementation to verify both sequence and acknowledgement numbers prior to accepting a RST control flag as valid, most TCP stack implementations check only that the sequence number is within the window. This allows connections to be reset with much less effort than previously believed. This risk is compounded by the easy prediction of source port selection used in TCP connections.

Connections can be closed by FIN also. The attacker constructs a spoofed FIN segment. It will have the correct SEQ numbers so that it is accepted by the targeted host. This host would believe the (spoofed) sender had no data left. Any segments that may follow from the legitimate sender would be ignored as bogus. The rest of the four-way handshake is also supplied by the attacker.

Connection Hijacking

Suppose X has initiated a TCP connection to Y. An attacker Z can take over this connection. Z can send segments to Y spoofing the source address as X, at a time when X was silent. Y would accept these data and update ACK numbers. X may subsequently continue to send its segments using old SEQ numbers, as it is unaware of the intervention of Z. As a result, subsequent segments from X are discarded by Y. The attacker Z is now effectively impersonating X, using "correct" SEQ/ACK numbers from the perspective of Y. As a result, Z has hijacked the connection: host X is confused, whereas Y thinks nothing is wrong as Z sends "correctly synchronized" segments to Y.

If the hijacked connection was running an interactive shell, Z can execute any arbitrary command that X could. Having accomplished his deed, a clever hijacker would bow out gracefully by monitoring the true X. He would cause the SEQ numbers of X to match the ACK numbers of Y by sending to X a segment that it generates of appropriate length, spoofing the sender as Y, using the ACK numbers that X would accept.

Floods and Storms

There have been several attacks that generate enormous numbers of packets rendering (portions of) a network ineffective. The attackers send source spoofed packets to intermediary machines. These amplify the numbers of packets into a "storm."

The SYN flood attack first occurred in 1996, and many systems in 2006 can be brought down. In the TCP protocol as designed, there is no limit set on the time to wait after receiving the SYN in the three-way handshake. An attacker initiates many connection requests with spoofed source addresses to the victim machine. The victim machine maintains data related to the connection being attempted in its memory. The SYN+ACK segments that the victim host sends are not replied to. Once the limit of such half-open connections is reached, the victim host will refuse further connection establishment attempts from any host until a partially opened connection in the queue is completed or times out. This effectively removes a host from the network for several seconds, making it useful at least as a stepping tool to other attacks, such as IP spoofing.

ACK storms are generated in the hijack technique described previously. A host Y, when it receives segments from X after a hijack has ended, will find the segments of X to be out of order. TCP requires that Y must send an immediate reply with an ACK number that it expects. The same behavior is expected of X. So, X and Y send each other ACK messages that may never end.

Legitimate applications or OS services can generate a storm of packets. On many systems, the standard services known as `chargen` that listens typically at port 19 and `echo` that listens typically at port 7 are enabled. `Chargen` sends an unending stream of characters intended to be used as test data for terminals. The `echo` service just echoes what it receives. It is intended to be used for testing reachability, identifying routing problems, and so on. An attacker sends a packet to the port 19 with the source address spoofed to a broadcast address and the source port spoofed to 7. The `chargen` stream is sent to the broadcast

address and hence reaches many machines on port 7. Each of these machines will echo back to the victim's port 19. This ping-pong action generates a storm of packets.

Congestion Control Attacks

Simple attacks by misbehaving receivers that send spurious ACKs were described in 1999 that drive a standard TCP sender arbitrarily fast by defeating TCP congestion control without losing end-to-end reliability.

The so-called Shrew DoS Attacks (2003) are examples that exploit omissions of important details in the design of the congestion control algorithms. They attempt to deny band width to legitimate TCP flows while sending at sufficiently low average rate to elude detection. These low-rate TCP attacks send a periodic short burst of segments that exploits the homogeneity of the RTO and forces all affected TCP flows to back off and enter the retransmission time-out state. This attack is difficult to identify because attack patterns are many.

Attacks via ICMP

In 2005, several blind connection-reset, blind throughput-reduction, and blind performance-degrading attacks were reported. These were all based on malicious ICMP messages. Note that the RFC 792 of ICMP does not recommend any kind of validation checks on the received ICMP error messages. All these attacks can be performed even being off-path, and without the need to sniff the packets of the attacked TCP connection.

TCP/IP Traffic Scrubbing

Scrubbing refers to forcing the TCP/IP traffic to obey all the rules of the RFCs. Reserved fields can be set to a random value; illegal combinations of flags are checked, and so on. Scrubbing is expected to be done not only at the originating hosts but also on the routers and especially in firewalls. Scrubbing adds to the computational burden of the hosts. Unfortunately, scrubbing may disrupt interoperability because of hidden assumptions made by programs beyond the specifications of the RFCs.

ROUTING

When the source *S* and the destination *D* are on the same network, we have direct delivery of an IP datagram that does not involve routing. When the two hosts are not on the same network, there can be multiple paths, in general, between *S* and *D*. Because of failures, maintenance, and other reasons, the intermediate nodes, known as routers, may come on or off during the delivery of packets. Note that consecutive packets sent by *S* to *D* may have to travel

entirely disjoint routes depending on how the network is connected at the moment.

Routing algorithms and protocols discover routes that the datagram can take from *S* to various routers ultimately arriving at *D*.

Routers

Routers are specialized computer systems whose primary function (often their sole function) is to route network traffic. The typical network host has only one NIC and hence is on only one network; sending and receiving of network traffic not intended for it is secondary to its main functionality. Routers have multiple NICs, each on a separate network. A router examines the destination IP address of a packet, consults its routing tables, and sends the packet on the network connected to the final destination or the next router.

Routers are network layer (OSI layer 3) devices. Note that a router may run several routing protocols simultaneously.

Routing Tables

Network hosts (including routers) have routing tables that record information regarding where to deliver a packet next so that definite progress is made in moving the packet closer to its final destination. It can be visualized as a table of just two columns: To send the packet to a destination given in column 1, send the packet to the *next hop* whose IP address is given in column 2. Such a table would have to list all possible destinations. Table 2 shows the actual routing table of a “simple” host that has three network cards named *eth0* . . . *eth2*.

Given the destination IP address *d* of a datagram, the routing module of the IP layer scans the rows of the table for a *match* where the Destination[*r*] value of that row *r* equals *d* & Mask[*r*], the result of *d* bit-wise-AND-ed with the mask in that row. The *next-hop* *n* is then Gateway[*r*]. If *n* is zero, the datagram is delivered direct; *d* and the source address are on the same network. If *n* is nonzero, the datagram is delivered to the IP address *n*. The last row has both mask and destination set to zero. This catch-all default row indicates the next hop IP address for any packet whose destination address does not match any other row. After the next-hop IP address is determined, the router uses the lower layer address (such as the Ethernet MAC) to deliver the packet to the next host.

The Flags (refer to Table 2) indicate whether the device of the row is Up or not, Gateway or not, and so on. The metric column shows a cost number for datagrams going

Table 2: Routing Table of a Simple Host with Three NICs

Mask	Destination	Gateway	Flags	Metric	Ref	Use	NIC
255.255.255.0	192.168.17.0	0.0.0.0	U	0	0	0	eth0
255.255.255.0	130.102.12.0	0.0.0.0	U	0	0	0	eth1
0.0.0.0	0.0.0.0	192.168.17.111	UG	0	0	0	eth2

through that row. The metric can quantify delay, throughput, and so on.

Routing Protocols

The routing tables of real routers are considerably more complex than the preceding. For example, they are structured to permit the use of longest CIDR prefix match, which can (i) override routes to large networks with more specific host or network routes, and (ii) aggregate routes to individual destinations into larger network addresses.

The routing table of an ordinary host is tiny and rarely changes from boot-up to shut down. The tables of routers on the Internet, however, are large (tens of thousands of rows) and must be dynamically adjustable to changing Internet conditions, perhaps by the millisecond. Routing protocols keep the routing tables up-to-date. The structure and content of the routing tables depend on the protocol.

Interior gateway protocols (IGP) maintain the routing tables within an *autonomous* system, that is, a network within the control of a corporation, university, or an ISP. Exterior gateway protocols (EGP) maintain the routing information among autonomous networks.

Globally consistent routing information is achieved by routing *arbiter* database of reachability information that is replicated by route servers at network access points where autonomous systems connect.

Interior Gateway Protocols: RIP and OSPF

Routing information protocol (RIP) and open shortest path first (OSPF) are examples of IGPs.

RIP (RFC 2453, 1998) is based on the *distance vector* routing method, which represents the internetwork as a graph G of nodes and edges, and computes shortest paths from the source node to other nodes. Hop count is the number of edges on a path to a destination. A path between two nodes S and D may be defined as the shortest among many paths from S to D based on hop count, minimum delay, and so on. RIP maintains the routing table with rows for each destination network it has encountered along with the hop count, and so on, obtained from G . RIP periodically propagates, as unsolicited responses, the contents of its table to neighboring routers. RIP-based routers receive these responses and update their own tables.

RIP messages are UDP transported.

RIP is easy to implement but does not scale well with the number of nodes. Route changes may result in tables not stabilizing, even forming routing loops, and some routers may have incorrect rows at any given time. Also, the number of RIP messages is proportional to the number of networks.

OSPF (RFC 2328, 1998) is based on *link states*. Two routers are said to be *linked* if they can communicate directly. The link is *up* if both are alive and reachable; otherwise, the link is *down*. An OSPF-based router periodically broadcasts the status of all its links. Link status messages propagate unchanged. OSPF-based routers listen to these messages, and recompute shortest paths whenever there is a link status change. OSPF messages are encapsulated in IP.

Each OSPF-router computes the status of links independently of other routers. Routing table updates will converge. The number of messages depends only on the number of links of a router, not on the number of networks. Thus, OSPF scales better than RIP.

Exterior Gateway Protocol: BGP

BGP4 (RFC 4271, 2006) is the most widely deployed of the exterior gateway protocols (Stewart 1999). Each autonomous system (AS) designates one router, typically at the border, on its behalf. BGP maintains routing information among these routers. BGP runs in two modes: Exterior BGP is run between different AS, and Interior BGP is run between BGP routers in the same AS. BGP messages are TCP transported.

BGP uses ideas from both distance vector and link status methods and extends them into path vectors described later. BGP routers collect routing information from other BGP routers, and from within their own autonomous systems through RIP and/or OSPF, and pass the combined information to their BGP router peers.

BGP has four message types. An OPEN message establishes a connection to a BGP peer, which also authenticates the sender. UPDATE messages communicate reachability information. KEEP-ALIVE messages actively test peer connectivity. NOTIFICATION messages both control and report on errors.

A BGP UPDATE message contains withdrawals of destinations that are now unreachable and *path attributes* to newly reachable destinations. The path attributes can specify seven types of information: (i) the origin of this information, (ii) list of autonomous systems that the path goes through, (iii) the next hop, (iv) multi-exit discriminator (MED) which suggests a preferred route into the AS that is advertising, (v) a local preference number that indicates preference for an exit point from the local AS that has many exits, (vi) ATOMIC_AGGREGATE, and (vii) AGGREGATOR. Full information is sent only once to a newly acquired peer, and later update messages carry only the incremental changes.

A BGP router R conceptually has three routing information tables/bases (RIB). All information received in UPDATE messages is entered into the RIB-IN table. RIB-LOCAL holds the routes that R has selected for use by R 's own AS. R analyzes the data of RIB-IN in the context of policies set by its administrator and may or may not update RIB-LOCAL. Among the multiple advertisements that it receives for the same route, BGP selects one path as the best route and inserts it into RIB-LOCAL. Contents of RIB-OUT are extracted from RIB-LOCAL to be disseminated to peers.

The best route is chosen based on path attributes; delay, bandwidth, or latency does not matter. A typical selection is as follows. If the path specifies a next hop that is inaccessible, drop the update. Select the path with the largest local preference. If the local preferences are the same, prefer the path that was originated by BGP running on this router. If no route was originated, prefer the route that has the shortest AS path. If all paths have the same AS path length, prefer the path with the lowest origin type (where $IGP < BGP < \text{"incomplete"}$). If the origin codes are the same, prefer the path with the lowest MED.

If the paths have the same MED, prefer the external path over the internal path. If the paths are still the same, prefer the path through the closest IGP neighbor. As a final tie breaker, select the path with the lowest IP address, as specified by the BGP router ID.

IGPs may converge faster, but an IGP does not scale up. Also, through the path attributes, BGP has inherent support for routing policies.

Route Spoofing

Several routing spoofs have become known.

An attacker can send a specially crafted ICMP redirect packet with the source address set to the regular router. The packet also contains the “new” router to use. An ICMP route redirect is normally sent by the default router to indicate that there is a shorter route to a specific destination. A host adds a host-route entry to its routing table after some checking, all of which is ineffective. Unlike ARP cache entries, host route entries do not expire. Name servers are obvious targets for this attack.

RIP-based attacks work by broadcasting illegitimate routing information to passive RIP hosts and routers. In both of these cases, the redirection can be made to any host chosen by the attacker.

Source routing allows the sending host to choose a route that a packet must travel to get to its destination. Traffic coming back to that host will take the reverse route. The attacker designs a route so that the packets go through his site.

A compromised BGP router can modify, drop, or introduce fake updates. Also, there are several assumptions underlying the UPDATE messages, such as (i) each AS along the path is authorized by the preceding AS to advertise the prefixes, (ii) the first AS in the path is authorized to advertise the prefixes by the holder of the prefixes, and (iii) a route is withdrawn only by the neighbor AS that advertised it. When these assumptions are invalid, BGP is vulnerable to many forms of attack.

BGP relies on TCP to maintain persistent sessions (Butler et al. 2005). The ISN-related vulnerability in TCP

allows remote attackers to terminate these sessions. CERT advisory VU#415294 (2004) notes that sustained exploitation of this vulnerability could lead to a denial-of-service condition affecting a large segment of the Internet.

INFRASTRUCTURE PROTOCOLS

In this section, we describe DNS, ARP, RARP, DHCP, and SNMP that can be considered “infrastructure” protocols. The primary purpose of these protocols is to support other protocols.

Domain Name Service (DNS)

Because of the mnemonic value, humans prefer to work with host names such as `gamma.cs.wright.edu`, rather than its IP address `130.108.2.22`, where `gamma` is the name of the host, and `cs.wright.edu` is the name of the domain the host is in. The primary function of DNS is to map such a name into its IP address.

The DNS name space is a tree hierarchy (RFC 1035) as shown in Figure 13. The top most subtrees are the top-level domains such as `.com`, `.edu`, `.net`, and `.org`, and the country code domains such as `.us` and `.in`. Subtrees of these are known as sub domains. The leaves are the individual hosts. A *fully qualified domain name* is the sequence of labels, separated by a dot, on the path from a node to the root of the tree.

The top-level domains (2006) are `ac`, `ad`, `ae`, `aero`, `af`, `ag`, `ai`, `al`, `am`, `an`, `ao`, `aq`, `ar`, `arpa`, `as`, `at`, `au`, `aw`, `az`, `ba`, `bb`, `bd`, `be`, `bf`, `bg`, `bh`, `bi`, `biz`, `bj`, `bm`, `bn`, `bo`, `br`, `bs`, `bt`, `bv`, `bw`, `by`, `bz`, `ca`, `cat`, `cc`, `cd`, `cf`, `cg`, `ch`, `ci`, `ck`, `cl`, `cm`, `cn`, `co`, `com`, `coop`, `cr`, `cu`, `cv`, `cx`, `cy`, `cz`, `de`, `dj`, `dk`, `dm`, `do`, `dz`, `ec`, `edu`, `ee`, `eg`, `er`, `es`, `et`, `eu`, `fi`, `fj`, `fk`, `fm`, `fo`, `fr`, `ga`, `gb`, `gd`, `ge`, `gf`, `gg`, `gh`, `gi`, `gl`, `gm`, `gn`, `gov`, `gp`, `gq`, `gr`, `gs`, `gt`, `gu`, `gw`, `gy`, `hk`, `hm`, `hn`, `hr`, `ht`, `hu`, `id`, `ie`, `il`, `im`, `in`, `info`, `int`, `io`, `iq`, `ir`, `is`, `it`, `je`, `jm`, `jo`, `jobs`, `jp`, `ke`, `kg`, `kh`, `ki`, `km`, `kn`, `kr`, `kw`, `ky`, `kz`, `la`, `lb`, `lc`, `li`,

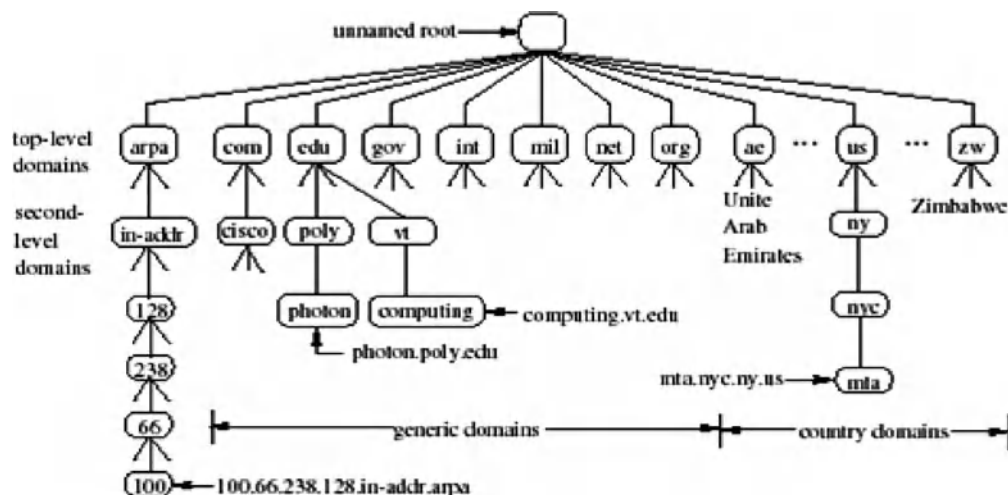

Figure 13: Domain name hierarchy

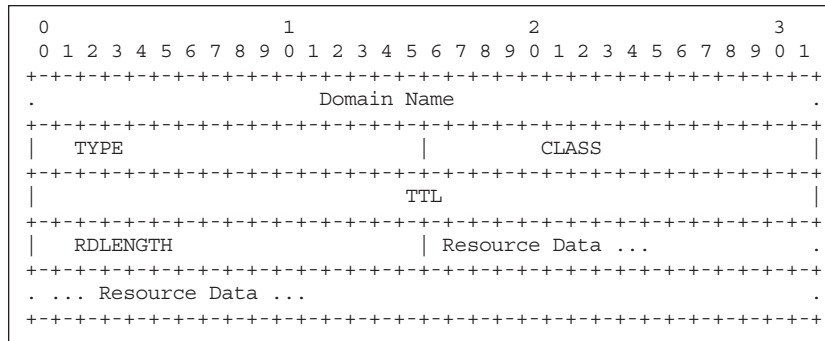

Figure14: Resource record

lk, lr, ls, lt, lu, lv, ly, ma, mc, md, mg, mh, mil, mk, ml, mm, mo, mobi mp, mq, mr, ms, mt, mu, museum, mv, mw, mx, my, mz, na, name, nc, ne, net, nf, ng, ni, nl no, np, nr, nu, nz, om, org, pa, pe, pf, pg, ph, pk, pl, pm, pn, pr, pro, ps, pt, pw, py, qa re, ro, ru, rw, sa, sb, sc, sd, se, sg, sh, si, sj, sk, sl, sm, sn, so, sr, st, su, sv, sy, sz, tc, td, tf, tg, th, tj, tk, tl, tm, tn, to, tp, tr, travel, tt, tv, tw, tz, ua, ug, uk, um, us, uy, uz, va, vc, ve, vg, vi, vn, vu, wf, ws, ye, yt, yu, za, zm, and zw.

Of these, the two-letter names are country domains. The top-level domain *arpa* is an *inverse domain* used to map an IP address to its name.

The mapping of names to addresses is not one-to-one. It is possible to associate a name with multiple IP addresses, thus providing load distribution. A single IP address can be associated with multiple names, one being a *canonical* name and others perhaps more mnemonic, and thus providing host aliasing.

DNS Servers

The domain name space is maintained as a database distributed over several *domain name servers*. A server can delegate the maintenance of any subdomain to another server. A delegated subdomain in the DNS is called a *zone*. The parent server keeps track of such delegations. Each name server has authoritative information about one or more zones. It may also have cached, but non authoritative, data about other parts of the database. A name server marks its responses to queries as authoritative or not.

A server whose zone is the entire tree is known as a *root server*. There are 13 root servers (in 2006; visit www.root-servers.org) located in the United States and other countries.

Resource Records

The database is a collection of *resource records* (Figure 14), each of which contains a domain name and four attributes. (i) The *record type* identifies what is stored in the data value. (ii) The *class* attribute of the record is "IN" for Internet. (iii) The time-to-live (TTL) value indicates how long a nonauthoritative name server can cache the record.

Some record types are A, AAAA, MX, and PTR. The data of an A record type is an IP address, of an AAAA record is an IPv6 address, of an MX record is the canonical host name of the mail server and its IP address, and of a PTR record is a pointer used to map an IP address to a domain name.

Name Resolution

The DNS *resolver* is a piece of software. Every host is configured with at least one local name server N if it is to find hosts not listed in the `etc/hosts` file. Each host maintains a short cache table that maps fully qualified domain names to IP addresses. When a name is not found in either this file or this cache, the host enquires with N via the DNS protocol using the resolver. TCP is used for zone transfers, UDP is used for look-ups, connecting to server port 53. The protocol is stateless—all the information needed is contained in a single message.

The primary function of DNS is to answer a query to translate a fully qualified domain name into its IP address. This is done by retrieving the A record. A reverse look-up (also called an inverse query) is to find the host name given the IP address. This is done by retrieving the PTR record. Some network services use this to verify the identity of the client host.

An *iterative* DNS query to a name server D receives a reply with either the answer or the IP address of the next name server. If the name is in the local zone, the local name server N can respond to a query directly. Otherwise, N queries one of the root servers. The root server gives a *referral* with a list of name servers for the top-level domain of the query. N now queries a name server on this list and receives a list of name servers for the second-level domain name. The process repeats until N receives the address for the domain name. N then caches the record and returns the address or other DNS data to the querying host.

A *recursive* DNS query to D will make D obtain the requested mapping on behalf of the querying host. If D does not have the answer, it forwards the query to the next name server in the chain, and so on until either an answer is found or all servers are queried and hence returns an error code. Because recursive look-ups take longer and need to store many records, it is more efficient to provide a recursive DNS server for LAN users and an iterative server for Internet users.

Security of DNS

The DNS answers that a host receives may have come from an attacker who sniffs a query and answers it with misleading data faster than the legitimate name server answers. The attacked host may in fact be a DNS server. Such DNS spoofing results in DNS cache poisoning, and all the clients of this server will receive false answers.

DNS zone transfers help map the targeted network during the reconnaissance stage of an attack.

The DNS protocol is improved in the DNSSEC (DNS security extensions), which is expected to be deployed widely. DNSSEC provides (i) origin authentication of DNS data, (ii) data integrity, and (iii) authenticated denial of existence. The answers in DNSSEC are digitally signed. Note that DNSSEC does not provide confidentiality of data.

The BIND (bounding-interval-length-dependent) package is a widely deployed implementation of DNS. Unfortunately, this otherwise highly capable software, in many releases over the years, has had much vulnerability of its own that allowed remote attackers to launch denial-of-service attacks, hijack domain names, or use vulnerable DNS servers to gain access to other systems.

Address Resolution Protocol (ARP)

ARP (RFC 826, 1982) is typically used to determine the Ethernet MAC address of a device whose IP address is known. This needs to be done only for outgoing IP packets because IP datagrams must be Ethernet framed with the destination hardware address. The translation is performed with a table look-up.

Reverse ARP (RARP) (RFC 903) allows a host to discover its own IP address by broadcasting the Ethernet address and expecting a server to reply with the IP address.

ARP is a network layer (OSI layer 3) protocol, but it does not use an IP header. It has its own packet format as shown in Figure 15. The ARP request packet has 0s in the target hardware address fields. It is broadcast on the local LAN without needing to be routed. The destination host sends back an ARP reply with its hardware address

Table 3: A Small Portion of an ARP Cache

IP address	Ethernet address
130.108.2.23	08-00-69-05-28-99
130.108.2.1	00-10-2f-fe-c4-00
130.108.2.27	08-00-69-0d-99-12
130.108.2.20	08-00-69-11-cf-b9
130.108.2.10	00-60-cf-21-2c-4b
192.168.17.221	00-50-ba-5f-85-56
192.168.17.112	00-A0-C5-E5-7C-6E

so that the IP datagram can now be forwarded to it by the router. An ARP response packet has the sender/target field contents swapped as compared to the request.

ARP Cache

An OS maintains a table called the ARP cache (see Table 3). The cache accumulates as the host continues to network. If the ARP cache does not have an entry for an IP address, the outgoing IP packet is queued, and an ARP request packet that effectively requests “If your IP address matches this target IP address, then please let me know your Ethernet address” is broadcast. After the table is updated because of receiving a response, all the queued IP packets can be sent.

The entries in the table expire after a set time period in order to account for possible hardware address changes for the same IP address. This change may have happened, for example, because of the NIC being replaced.

ARP Poisoning

ARP poisoning is an attack technique that corrupts the ARP cache with wrong Ethernet addresses for some IP addresses. An attacker accomplishes this by sending an

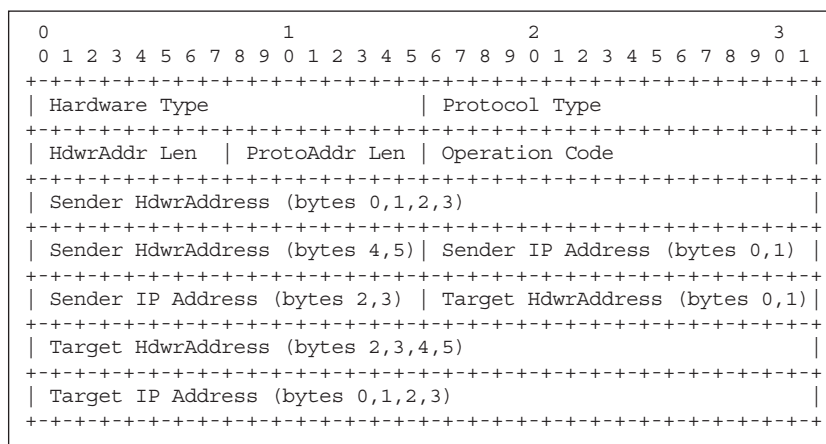

Figure 15: An ARP request/response packet

ARP response packet that is deliberately constructed with a “wrong” MAC address. The ARP is a stateless protocol. Thus, a machine receiving an ARP response cannot determine if the response is because of a request it sent or not.

ARP poisoning enables the so-called man-in-the-middle attack that can defeat cryptographic communications such as SSH, SSL, and IPsec. An attacker on machine M inserts himself between two hosts A and B by (1) poisoning A so that B's IP address is associated with M's MAC address, (2) poisoning B so that A's address is associated with M's MAC address, and (3) relaying the packets M receives A from/to B.

ARP packets are not routed, and this makes it very rewarding to the attacker if a router can be ARP poisoned.

Dynamic Host Configuration Protocol (DHCP)

A typical host will invoke a DHCP (RFC 2131, 1997) client program soon after booting into the OS to configure its network. A DHCP server delivers host-specific configuration parameters, such as an IP address, a subnet mask, a list of default routers, TTL, and MTU. An OS utility then associates the IP address with a host name.

DHCP assumes that the IP layer software will pass the packets delivered to the NIC of the host even though it has not been assigned an IP address yet. A DHCP client broadcasts (i.e., the IP destination address is 255.255.255.255) a request in a UDP packet containing its own MAC address. A DHCP server process listens to such requests, and IP-broadcasts or hardware-unicasts a reply that contains the configuration parameters.

DHCP has three mechanisms for IP address allocation. In automatic allocation, DHCP assigns a permanent IP address to a client. In dynamic allocation, DHCP leases an IP address to a client for a limited period (or until the client explicitly relinquishes the address). In manual allocation, the IP address is assigned manually but is conveyed to the client via DHCP. Dynamic allocation is the only one of the three mechanisms that allows automatic reuse by a different host of an address that is no longer needed by the client to which it was assigned.

Simple Network Management Protocol (SNMP)

SNMP (RFC 3411) allows network managers to see how the network is functioning and control it. A management agent (MA) runs as a server process on each managed device. A network administrator invokes a management client (MC) program on his console. The MC can send queries as IP datagrams to the MA obtaining status information, or commands to alter the conditions in the managed device. Network devices that are simple enough to not run an agent are known as unmanaged devices.

All SNMP operations can be cast as a sequence of one or more of (i) retrieve the current value of a management information base (MIB) variable, or (ii) store a value for a variable. For example, an immediate reboot of a managed device can be caused by storing a 0 in the MIB variable that gives the time until the next reboot.

Transport Layer Security (SSL/TLS)

Transport layer security (RFC 4346, (2006) provides privacy and data integrity. Privacy refers to a third party being unable to get unencrypted versions of messages between two parties. Integrity refers to the receiver being able to rely that the messages have not been tampered with in transit. TLS was referred to as secure socket layer (SSL) before becoming a standard.

TLS is implemented as a layer above the TCP. Higher-level protocols can layer on top of the TLS transparently. Programs that used TCP can be readily rewritten to use TLS instead. HTTPS and modern implementations of such protocols as FTP, telnet, POP3S, and SMTP are based on TLS. The TLS standard, however, does not specify how other protocols add security with TLS; the decisions on how to initiate TLS handshaking and how to interpret the authentication certificates exchanged are left up to the judgment of the designers and implementers of protocols that run on top of TLS. For example, it is possible to switch to a new TLS connection on different ports, or initiate TLS service on the same connection by issuing a special command token such as STARTTLS done by Enhanced SMTP.

TLS is composed of Record and Handshake protocols. The Record protocol provides connections that are private by encrypting data using symmetric cryptography (Stallings 2005). The encryption keys are generated for each connection based on a secret negotiated by the TLS Handshake protocol. The connection is tamper-proof. Messages are integrity checked using a keyed message authentication code based on secure hash functions such as SHA and MD5.

The TLS Handshake protocol provides (i) authentication of the peer's identity using public key cryptography, such as RSA, and DSS; (ii) secure negotiation of a shared secret even if an attacker is present in the middle of the connection; and (iii) reliable negotiation messages that no attacker can modify without being detected by the parties to the communication.

Authentication Protocols

Authentication is the process of verifying the credentials of a user, a host (node), or a service. Authentication protocols enable such procedures by sending or receiving messages in encrypted form. Authentication without encryption is like having a paper-thin door to a house. Some well-known authentication protocols are Kerberos, RADIUS, PAP, and CHAP.

PAP and CHAP

PPP uses PAP or CHAP for authentication. PAP (password authentication protocol; RFC 1334) is a two-way handshake protocol. It sends the user name and password in plain text, obviously vulnerable to sniffing. CHAP (challenge handshake authentication protocol; RFC 1944) is a three-way handshake protocol. The CHAP server sends the user client a challenge, which is a randomly generated sequence of bytes unique to this authentication session. The client encrypts the challenge using a previously issued secret key that is shared by both the client and CHAP server. The result, called a response, is then

returned to the CHAP server. The CHAP server performs the same operation on the challenge it sent with the shared secret key and compares its results, the expected response, with the response received from the client. If they are the same, the client is assumed authentic.

Radius

Remote authentication dial-in user service (RADIUS; RFC 2865) is a widely used protocol that provides authentication, authorization, and accounting services for managing access to resources, in particular wireless or dialup Internet access. The protocol itself is quite simple and has been implemented many times. A RADIUS client running on a network access server machine collects the user name and password and sends them as an access request to a server. The RADIUS server has a database of user names associated with their passwords through which it validates the user. The client and the RADIUS server have a shared secret that is used to encrypt portions of their messages.

APPLICATIONS

There are numerous applications are based on TCP/IP. In this section, we describe briefly several protocols and applications that belong in the applications (OSI 7) layer. Several chapters in this book are devoted to applications, for example, “Streaming Multimedia,” “Virtual Private Networks,” “Computer and Network Authentication,” “Password Authentication,” “Computer Network Management,” and “E-mail and Instant Messaging.”

Nearly all network applications are based on a client/server architecture where one process, the client, requests services from a second process, the server. Typically, the client and server processes are on different machines, but they need not be.

Virtual Private Networks (VPN)

Virtual private networks (VPN) enable secure communication through public networks using cryptographic channels. Point-to-point tunneling protocol (PPTP) is used in providing VPNs. After the initial PPP connection to a PPTP server, a PPTP tunnel (see Glossary), and a PPTP control connection are created. PPTP uses an enhanced generic routing encapsulation (GRE) mechanism to provide a flow- and congestion-controlled encapsulated datagram service for carrying PPP packets. See Chapter 181 for details on VPNs.

Network File System

NFS protocol (RFC 3530, 2003) makes the file volumes located on a file server available, using UDP or TCP, to client machines.

File volume mounting, file open, read, write, and close operations are standard system calls in OSs. The mount operation can detect an attempt at mounting a remote directory via NFS. Such a remote mount operation sends client machine information and the path name of a remote directory being requested to the NFS server process. The server returns a mount handle, assuming

the file volume export permissions are positive for this client. File open, read, write, and close operations on the client machine specify path names relative to the mount point as if they are local.

File Transfer Protocol (FTP)

The primary function of FTP (RFC 959, 1985) is to place a copy of a local file on a remote machine (called PUT, popularly known as uploading) or bring a copy of a remote file (called GET, popularly known as downloading). Additionally, there are a few directory maintenance commands.

FTP uses two TCP connections, one called the *control* connection and the other the *data* connection. The FTP client opens a control connection to port 21 of the FTP server machine. On the control connection, the client can issue commands that change various settings of the FTP session. The GET command requests for the transfer of files that the server has, and the PUT command requests the server to receive and store the files that the client is about to send. All content transfer occurs on the data connection. This connection persists the entire session.

The data connection can be opened in one of two modes. In the active mode FTP, the server initiates a data connection as needed from its port 20 to a port whose number is supplied by the client on the control connection via the PORT command.

In the passive mode FTP, the server informs the client a port number higher than 1024 that the server has chosen, to which the client initiates a data connection. Passive FTP is useful in firewall setups that forbid initiation of a connection from an external host (the FTP server) to the internal network (the FTP client).

FTP is an insecure protocol. The messages between the client and the server over both the connections are in the clear text. In particular, the user name, password, and all file data are transmitted in the unencrypted form. This comment does not apply to SSL-based FTP.

Telnet

Telnet belongs to a class of programs called remote shells that provide a virtual terminal to a command line shell running on a remote machine.

Telnet (RFC 854, 1983) establishes a TCP connection with a telnet server on the reserved port 23 and passes the keystrokes of the telnet client to the server and accepts the output of the server as characters to be displayed on the client. The server presents these keystrokes as input received from a pseudo terminal to the OS hosting the telnet server.

Telnet defines a network virtual terminal (NVT) format as that which permits interoperability with machines that use different characters for common operations such as terminating a line and interrupting a run-away process. The telnet client typically maps the signal-generating keys of the keyboard to invoke the corresponding control functions of the NVT. The control functions are encoded as escape sequences of 2 bytes, the IAC (255), followed by the 1-byte code of the control function. Telnet uses the URGENT DATA mechanism of TCP to send control functions so that the telnet server can respond appropriately.

Telnet is an insecure protocol. User name, password, and all data in both directions are transmitted in the unencrypted form. This comment does not apply to SSL-based telnet.

rlogin

The rlogin protocol (RFC 1282) operates by opening a TCP connection on the rlogin server machine at port 513. It is widely used between UNIX hosts because it provides transport of more of the UNIX terminal environment semantics than does the telnet protocol and because on many UNIX hosts it can be configured not to require user entry of passwords when connections originate from trusted hosts.

Rlogin is an insecure protocol. User name, password, and all data in both directions are transmitted in the unencrypted form.

Secure Shell

SSH (RFC 4251, 2006) provides the functionality of FTP, telnet, and rlogin but with greater security. There was a version called SSH-1; the version as defined in RFC 4251 is called SSH-2.

FTP, telnet, and rlogin send authentication information and data in the clear (i.e., unencrypted) and hence are easily compromised by network sniffers. In addition, their authentication of the host is simply the IP address. Consequently, utilities based on these protocols should not be used in situations where security is a concern.

There are three primary advantages in using SSH. (i) Telnet and rlogin do not authenticate the remote machine; SSH does. (ii) The password that the user types as part of the login ritual is sent as clear text by telnet and rlogin; SSH sends it encrypted. (iii) The data being sent and received by telnet and rlogin is also sent as clear text; SSH sends and receives it in encrypted form.

The main disadvantages are the following. (i) Encryption and decryption consumes computing and elapsed time. (ii) If the remote system has been legitimately reinstalled, and the installer was not careful to use the same authentication keys for the host, a false alarm may be raised. (iii) SSH is susceptible to man-in-the-middle attack.

SSH Architecture

SSH-2 protocol is dependent on SSH authentication protocol (RFC 4252), SSH transport layer protocol (RFC 4253), and SSH connection protocol (RFC 4254).

The transport protocol (SSH-TRANS) handles the cryptographic initial key exchange and authenticates the server, and sets up encryption and compression. The transport layer also arranges for key re-exchange during a long session. The functionality of the transport layer is comparable to TLS.

The authentication protocol (SSH-USERAUTH) authenticates the user to the SSH server process. It provides for a number of authentication methods and runs over SSH-TRANS.

The connection protocol (SSH-CONNECT) provides interactive login sessions, remote execution of commands,

forwarded TCP/IP connections, and forwarded X11 connections. SSH-CONNECT defines the concept of channels. A channel transfers data in both directions. A single SSH connection can simultaneously host multiple channels multiplexed into a single encrypted tunnel. Some channel types are (i) shell for terminal shells, `sftp`, `scp`, and execution of other commands; (ii) `direct-tcpip` for client-to-server forwarded connections; and (iii) `tcpip-forward` for server-to-client forwarded connections. SSH-CONNECT runs over SSH-TRANS and SSH-USERAUTH.

Host Authentication. During the first few steps of installing an OS on a machine, an authentication key pair for the host is generated using cryptographic algorithms. The pair consists of two rather large numbers that are coupled in the sense that any message encoded by one can be decoded by the other. Care should be taken to re-use this key pair whenever an OS is re-installed. The public key of the host is widely published. The private key is safe guarded.

The SSH client program verifies that it is talking to the real server by sending a message after encrypting using the public key of the SSH server machine. The server would decrypt using the private key it should have to obtain the original message.

The public key of the SSH server machine is obtained in one of two ways. (i) The client maintains a database of SSH server names and their public authentication keys that the server offers the first time an SSH session is opened to the server. Subsequent SSH sessions compare the authentication key offered by the server with that stored in the client database. (ii) The host name-to-key association is certified by a trusted certification authority (CA).

User Authentication. User authentication is client-driven. Several authentication methods are in wide use. (i) Password where the user types a password that is sent to the server through an encrypted channel. (ii) Public key, supporting at least DSA or RSA key pairs. (iii) Keyboard-interactive method (RFC 4256) where the server sends one or more prompts to enter information and the client displays them and sends back responses keyed in by the user. This is used in one-time password authentication, such as S/Key or SecurID.

Tunnels. The SSH-CONNECT protocol provides encrypted channels that can be used for setting up forwarding (tunneling) arbitrary TCP/IP ports and X11 connections. Suppose we have an SSH session for user U going between the client at host C and the server at host S. SSH can establish a tunnel to a host H connecting a TCP port *i* at C with a port *j* at H; that is, traffic sent to C:*i* will be delivered to H:*j* and vice versa. All traffic on this tunnel is encrypted.

Mail Protocols

Electronic mail existed “before Internet” but has become as common as the telephone due to it. E-mail now encompasses SMTP, POP, IMAP, and MIME. E-mail client programs such as Microsoft Outlook or Mozilla Thunderbird are made up of two components: a user agent (UA)

and a mail transfer agent (MTA). A UA program accepts, from a user, mail memos to be sent. The mail is delivered to a server by an MTA program using SMTP. Mail is received using the protocols POP or IMAP.

Mail Message Format

An e-mail consists of a message body, headers, and an envelope that includes the FROM and TO headers. An optional header line is REPLY-TO. The message body consists of text and attachments. The mail headers adhere to the standard format of Internet messages (RFC 2822). The headers are plain text lines, each line made up of a keyword, a colon, and a value. Certain keywords must appear among the headers. For example, a TO address header is required. This specifies the e-mail address of the recipient in the form of `mbx@dnm`, where `mbx` is the name of a mail box on the local machine, and `dnm` is the domain name of the destination.

SMTP

Simple mail transfer protocol (RFC 2821, 2001) defines the commands and replies among mail transfer agent (MTA) clients and servers. An MTA client transfers the mail spooled on the local machine across the Internet to an MTA server. The transfer can occur in a single connection between the original mail-sender and the final mail-recipient, or may go through intermediary systems known as MTA relays.

SMTP is specified to require only a reliable ordered data stream channel. Modern e-mail clients use SSL/TLS as the transport.

POP

Post office protocol (POP) is used to send/receive e-mail from a server. POP2 requires SMTP to send messages. POP3 can be used with or without SMTP. POP downloads entire message bodies and can optionally keep the messages on the server. A user reading e-mail from multiple machines may not have a consistent view of his messages.

IMAP

Internet message access protocol (IMAP) is a protocol for accessing e-mail while it is still located on the server. IMAP4 supports encrypted login mechanisms and SSL for the transport.

MIME

Multipurpose Internet mail extensions (MIME) defines the format of messages to allow for (i) textual message bodies in character sets other than US-ASCII, (ii) an extensible set of different formats for non-textual message bodies, (iii) multi-part message bodies, and (iv) textual header information in character sets other than US-ASCII.

Hypertext Transfer Protocol (HTTP)

HTTP (RFC 2616, 1999) is at the core of the World Wide Web. The Web browser on a user's machine and the Web server on a machine somewhere on the Internet communicate via HTTP using TCP usually at port 80. HTTPS (RFC 2660, 1999) is a secure version of HTTP. A Web

browser displays a file of marked-up text with embedded commands following the syntactic requirements of the HTML. There are several ways of invoking these commands, the most common one being the mouse click. Most of the clickable commands displayed by a Web browser are the so-called links that associate a URL with a (visible piece of) text or graphic. URLs have the following syntax:

```
scheme://[userName[:password@]]serverMachineName[:port]/[path]/[resource][?parm1=parm&parm2= parmb]
```

A simple example of the above is `www.cs.wright.edu/~pmateti/InternetSecurity` where the scheme chosen is `http`, and the port defaults to 80. A click on such a link generates a request message from the browser to the Web server process running on the remote machine `www.cs.wright.edu`, whose name is obtained from the link clicked. The Web server maps the path `~pmateti/InternetSecurity` to a local file according to the rules of the Web server. This may be a preexisting file or generated on the fly. The server transmits a copy of this local file. The browser then displays the page it receives from the server.

HTTP Message Format

The request and response are created according to the HTTP message format, which happens to be a sequence of human-readable lines of text. The first line identifies the message as a request or response. The subsequent lines are known as header lines until an empty line is reached. Following the empty line are lines that constitute the "entity body." Each header line can be divided into two parts, a left- and right-hand side, separated by a colon. The left-hand side names various parameters. The right-hand side provides their values.

The request line has three components: a method (one of GET, POST, or HEAD), a URL, and the version number of HTTP (either 1.0 or 1.1) that the client understands. The GET method requests the content of a Web page. The POST method is used when the client sends data obtained from a user-filled HTML form. The HEAD method is used in program development.

The response line also contains three components: HTTP/version-number, a status code (such as the infamous 404), and a phrase (such as Not Found, OK, or Bad Request). The entity body in a response message is the data, such as the content of a Web page or an image, which the server sends.

Cookies

HTTP is stateless in that the HTTP server does not act differently to a specific request based on previous requests. Occasionally, a Web service wants to maintain a minor amount of historical record of previous requests. Cookies (RFC 2965) create a stateful session with HTTP requests and responses.

The response from a server can contain a header line such as "Set-cookie: value." The browser then creates a cookie stored on the browser's storage. In subsequent requests sent to the same server, the browser includes the header line "Cookie: value." Depending on the browser, cookies are stored in a database or as small files of text.

Encrypted Security Payload

The encrypted security payload (ESP) is an extension for data confidentiality and the prevention of easy decodability of information obtained through eavesdropping. IPv4 sends all its payload and headers in clear text. A determined attacker can install remote sniffers along every path that a communication uses from host B to host C and assemble full messages being sent at the application level. The IPsec protocol adds authentication and encryption. The IPv6 includes IPsec. The cryptographic protocols of IPsec provide authentication, encrypt data, and guarantee message integrity. It also provides for a key exchange protocol, such as the IKE (Internet key exchange) protocol.

Other Improvements over IPv4

Note that the following fields of IPv4 header (refer to Figure 7) are dropped: IHL, Type of Service, Identification, Flag, Offset, and Header Checksum. The simpler header of IPv6 improves routing efficiency, performance, and forwarding rate.

An IPv6 host that wants to auto-configure sends a link-local request for its configuration parameters to which a router should respond with a router advertisement packet. A host can also use DHCPv6 or be configured manually.

The sending IPv6 host uses a path MTU discovery technique and does the fragmentation. Unlike IPv4, the IPv6 routers along the way do not (further) fragment. Removal of this task and the check summing task contributes to improved router performance.

IPv4 to IPv6 Transition

Many current systems (including personal computers and routers) are “dual stack”; that is, they support both IPv4 and IPv6 simultaneously.

A device capable of both IPv4 and v6 can have a regular IPv6 address and another IPv4 compatible IPv6 address by prefixing the `i.j.k.l` IPv4 address with 96 zero bits; for brevity, such an IPv6 address is written as `::i.j.k.l`. A device capable of only IPv4 is IPv6-addressable by having its IPv4 address prefixed with a string of 80 zeroes followed by 16 ones; for brevity, such an IPv6 address is written as `::FFFF:i.j.k.l`.

IPv6 network islands that do not have a path between them communicate through an IPv4 tunnel by encapsulating IPv6 datagrams within IPv4 at the head-end of a tunnel and decapsulate at the tail-end. This requires configuring the tunnels. Such isolated nodes and networks can also use the “6to4” mechanism (RFC 3056) with the

addition of a 6to4 router at the borders. The IANA has permanently assigned `2002::/16` as a 6to4 prefix to IPv4 addresses, which provides a network prefix for the local IPv6 host or network. The IPv4 address is the endpoint for all external IPv4 connections. The 6to4 effectively uses a IPv4 network as a unicast point-to-point layer, requires no end-node reconfiguration, and requires minimal router configuration.

The 6bone was an IPv6 test bed to assist in the evolution and deployment of IPv6. It was phased out in June 2006.

ICMPv6

ICMPv6 (RFC 2463, 1998) is used by IPv6 to report errors encountered in processing packets, and to perform other network-layer functions. ICMPv6 is a required companion to IPv6. IGMP and ARP are merged into ICMPv6, and RARP is omitted.

Every ICMPv6 message (Figure 17) is preceded by an IPv6 header and zero or more IPv6 extension headers. ICMPv6 messages are either error messages or request/reply informational messages.

Error Messages

There are error messages in ICMPv6 corresponding to those in ICMPv4, except a source quench. The source-quench message is no longer needed because the Traffic Class Priority and Flow Label fields of IPv6 (Figure 16) are sufficient for congestion control purposes. Additionally, there is a new “Packet Too Big” message sent by a router when it receives an IPv6 datagram that is longer than the MTU of the outgoing link.

Request/Reply Messages

The Echo Request, Echo Reply, Router Advertisement, and Router Solicitation query messages are essentially as in ICMPv4. The ICMPv4 Timestamp Request and Address Mask Request messages are dropped.

Neighbor Discovery (ND)

ICMPv6 subsumes the functionality of ARP through the Neighbor Discovery (RFC 2461) protocol. ND uses ICMPv6 messages named Router Solicitation, Router Advertisement, Neighbor Solicitation, Neighbor Advertisement, and Redirect. Through these messages routers, next-hops, address prefixes, and parameters are discovered; IPv6 addresses are auto-configured; unreachability of neighbors and duplicate addresses are detected.

Figure 17: ICMPv6 packet

DHCPv6

The dynamic host configuration protocol for IPv6 (RFC 3315, 2003) is to IPv6 what DHCP was to IPv4. DHCPv6 enables DHCP servers to pass configuration parameters such as IPv6 network addresses to IPv6 nodes. It offers the capability of automatic allocation of reusable network addresses and additional configuration flexibility. This protocol is a stateful counterpart to IPv6 Stateless Address Auto Configuration (RFC 2462), and can be used separately or concurrently with the latter to obtain configuration parameters. With auto-configuration, every host that connects to the network can get an IPv6 address assigned and can use network resources.

Auto-configuration does not allow a network administrator to define admission control policies. Even in just assigning IPv6 addresses, auto-configuration is not appropriate in administrated infra structures, such as enterprise networks. In contrast, DHCPv6 servers provide means for securing access control to network resources by checking admission control policies. Note also that IPv6 auto-configuration does not cover information about further services in the network, for example, DNS. Many of the options commonly supported by DHCPv4 are supported also by DHCPv6.

A client obtains an IPv6 address and other parameters as follows. (i) Send a multicast Solicit message to find a DHCPv6 server and ask for a lease. (ii) Any server that can fulfill the client's request responds to it with an Advertise message. (iii) Choose one of the servers, and send a Request message asking to confirm the offered address and other parameters. (iv) The server responds with a Reply message to finalize the process. This four-message process can be reduced to two, where the client multicasts a Solicit message indicating that a server should respond back with a Reply message. A client who already has an IPv6 address multicasts an Information-Request message. A server with configuration information for the client sends back a Reply message. A DHCPv6 client renews its lease after a period of time by sending a Renew message.

CONCLUSION

The Internet and the World Wide Web are based on a suite of protocols and software collectively known as TCP/IP. It includes not only the transmission control protocol and Internet protocol but also other protocols such as UDP, ARP, DNS, and ICMP, and applications such as telnet, FTP, Secure Shell, and Web browsers and servers. We surveyed these topics starting from the four-layer Internet reference model to recent improvements in the implementations of the protocol stack and security.

GLOSSARY

Big Endian: A 32-bit integer is stored in four consecutively addressed bytes a , $a+1$, $a+2$, and $a+3$. In a big-endian system, the most significant byte of the integer is stored at a . In a little-endian system, the least significant byte is stored at a .

Byte: A byte is a sequence of 8 bits. Viewed as an unsigned number, it is in the range of 0 to 255. *See also octet.*

CERT: Advanced countries have a Computer Emergency Response Team that can assess network and computer security incidents and issue advisories. The site for USA is www.cert.org. It issues timely and authoritative alerts regarding computer exploits and has a comprehensive collection of guides on security.

Checksum: A checksum is a function of the sequence of bytes in a packet. It is used to detect errors that may have altered some of the numbers in the sequence. The IP checksum field is computed as the 16-bit 1 complement of the 1 complement sum of all 16-bit words in the header. For purposes of computing the checksum, the value of the checksum field is 0.

Client: The process that establishes connections for the purpose of sending requests.

Datagram: A sequence of bytes that constitutes the unit of transmission in the network layer (such as IP).

Frame: The unit of transmission at the data link layer, which may include a header and/or a trailer, along with some number of units of data.

Host: A device capable of sending and receiving data over a network. Often, it is a computer system with an NIC, but it can be a much simpler device.

Network: A collection of links in which the hosts are connected either directly or indirectly.

Network Applications: Programs that operate over a network.

Network Operating Systems: These systems have network software built in and are aware of byte order issues.

Node: A synonym for host.

Octet: An 8-bit quantity on older computer architectures where the smallest addressable unit of memory was a word (of sizes such as 36 or 60 bits) and not a byte.

Packet: A generic term used to designate any unit of data passed between communicating entities and is usually mapped to a frame.

Process: The dynamic entity that can be summarized as a "program during its execution on a computer system."

Program: A file of binary data in a certain rigid format that is specific to each platform, capable of being both a client and a server. Our use of these terms refers only to the role being performed by the program for a particular connection rather than to the program's capabilities in general.

Protocol: A formal and pre-agreed set of rules that govern the communications between two or more entities. The protocol determines the meaning of specific values occurring in specific positions in the stream, the type of error checking to be used, the data compression method, how the sender will indicate that it has finished sending a message, and how the receiver will indicate that it has received a message.

RFC: Request for Comments documents are Internet standards, proposed designs, and solutions published by researchers from universities and corporations soliciting feedback and archived at www.rfc-editor.org.

Server: A process that accepts connections to service requests by sending back responses. It is also called a daemon.

Spoofing: In IP spoofing, either the source or the destination is a fake address. In DNS spoofing, a query receives a fake response.

Tunneling: Sending packets of a certain protocol embedded in the packets of another protocol.

FURTHER READING

TCP/IP details are part of many university courses on computer networks. There are several textbooks. Of these, the three authoritative volumes of Comer's *Internetworking with TCP/IP* are classic technical references in the field aimed at the computer professional and the degree student. Volume I surveys TCP/IP and covers details of ARP, RARP, IP, TCP, UDP, RIP, DHCP, OSPF, and others. There are errata at www.cs.purdue.edu/homes/dec/tcpip1.errata.html. *The Internet Book: Everything You Need to Know about Computer Networking and How the Internet Works* is a gentler introduction. The books listed in the References section by Forouzan, Tanenbaum, and Kurose and Ross are also popular textbooks. The book by Stevens discusses from a programming point of view.

Routing protocols are discussed briefly in the aforementioned books. The books by Halabi and Doyle cover this topic extensively. BGP security is surveyed in the article by Butler et al.

HTTP and related issues are thoroughly discussed in the books of Krishnamurthy and Rexford, and Gourley and Totty.

The book by Denning and Denning is a high-level discussion of how the vulnerabilities in computer networks are affecting society. Mateti has an extensive Web site (www.cs.wright.edu/~pmateti/InternetSecurity) that has lab experiments and readings online. The book by Garfinkel and Spafford explores security from a practical UNIX systems view.

All the RFCs are archived at www.rfc-editor.org. The Usenet newsgroup `comp.protocols.tcp-ip` is an active group that maintains a frequently asked questions (FAQ) document that is worth reading. The Technical Committee on Computer Communications of the IEEE Web site (www.comsoc.org) maintains an extensive collection of conference listings. The *IEEE/ACM Transactions on Networking* is a peer-reviewed archival journal that publishes research articles.

INTRODUCTION

Electronic mail (e-mail) is one of the most popular network services nowadays. Most e-mail systems that send mail over the Internet use simple mail transfer protocol (SMTP) to send messages from one server to another. The mail delivery is a two-stage process that provides for mail instances when the network connection or the remote machine has failed (Comer 2005). For example, when a user does not have a permanent Internet connection, it should have a mailbox on a computer that does have such a connection. That computer must run the SMTP server and be able to always receive incoming mail. The mail messages can then be retrieved by the user from the mailbox with an e-mail client (installed on the user's machine) using either post office protocol (POP) or Internet message access protocol (IMAP). The computer with the permanent mailbox must run two servers: SMTP for accepting mail and POP/IMAP for retrieving mail. SMTP is also generally used to send messages from a mail client to a mail server in "host-based" (or Unix-based) mail systems, where a simple mbox utility might be on the same system [or via network file system (NFS) provided by Novell] for access without POP or IMAP.

This chapter describes the fundamentals of SMTP, elements of its client-server architecture (user agent, mail transfer agent, ports), request-response mechanism, commands, mail transfer phases, SMTP messages, multipurpose Internet mail extensions (MIME) for non-ASCII (American Standard Code for Information Interchange) data, e-mail delivery cases, mail access protocols (POP3 and IMAP4), SMTP software, some vulnerability and security issues, standards, associations, and organizations.

SMTP FUNDAMENTALS

SMTP, an application layer protocol, is used as the common mechanism for transporting electronic mail among different hosts within the transmission control protocol/Internet protocol (TCP/IP) suite. The history of SMTP has been described by Kozierok (2006). Under SMTP, a client SMTP process opens a TCP connection to a server SMTP process on a remote host and attempts to send mail across the connection. The server SMTP listens for a TCP connection on a specific port (25), and the client SMTP process initiates a connection on that port (Cisco SMTP 2006). When the TCP connection is successful, the two processes execute a simple request-response dialogue, defined by the SMTP protocol (see RFC 2821 and RFC 821 for details), in which the client process transmits the mail addresses of the originator and the recipient(s) for a message. When the server process accepts these mail addresses, the client process transmits the e-mail message. The message must contain a message header and message text ("body") formatted in accordance with RFC 2822 and RFC 822.

In February 1993, the SMTP Service Extensions standard (RFC 1425), which describes a process for adding new capabilities to extend how SMTP works while maintaining backward-compatibility with existing systems, was published. The extended SMTP (ESMTP) standard (RFC 1425) was revised in RFC 1651 in July 1994 and then RFC 1869 in November 1995. Particular SMTP extensions, such as message size declaration (RFC 1653 and RFC 1870), authentication (RFC 2554), and pipelining (RFC 2920), were defined later. In April 2001, revisions of RFC 821 and RFC 822 were published, as RFCs 2821 and 2822 respectively. The current base standard protocol for

SMTP (RFC 2821) incorporates the base protocol description (RFC 821) and the latest SMTP extensions (RFC 1869) and updates the description of the e-mail communication model to reflect changes of TCP/IP networks, especially the e-mail features built into the domain name system (DNS) (Kozierok 2006).

Mail that arrives via SMTP is forwarded to a remote server, or it is delivered to mailboxes on the local server. POP3 or IMAP allow users to download mail that is stored on the local server. The delivery of e-mail to a user's mailbox typically takes place via a mail delivery agent (MDA). The MDA software accepts incoming e-mail messages and distributes them to recipients' individual mailboxes (if the destination account is on the local machine), or forwards back to an SMTP server (if the destination is on a remote server) (Wikipedia 2006). On UNIX systems, /bin/mail is the most popular MDA. Many mail transfer agents (MTAs) have basic MDA functionality built in, but a dedicated MDA like procmail can provide more sophistication.

Most mail programs such as Eudora allow the client to specify both an SMTP server and a POP server. On UNIX-based systems, Sendmail is the most widely used SMTP server for e-mail. Sendmail includes a POP3 server and also comes in a version for Windows NT ("What is SMTP?", 2006). The MIME protocol defines one way files can be attached to SMTP messages. Microsoft Outlook and Netscape/Mozilla Communicator are some popular mail-agent programs on Window-based systems. The other functional and capable method of file attachment includes uuencode and uudecode techniques that are no longer in widespread use.

The X.400 International Telecommunication Union standard (Tanenbaum 2003) that defines transfer protocols for sending electronic mail between mail servers is used in Europe as an alternative to SMTP. Also, the message handling service (MHS) developed by Novell

is used for electronic mail on Netware networks ("What is SMTP?" 2006).

SMTP MODEL AND PROTOCOL

The SMTP model (RFC 821) supports both end-to-end (no intermediate message transfer agents [MTAs]) and store-and-forward mail delivery methods. The end-to-end method is used between organizations, and the store-and-forward method is chosen for operating within organizations that have TCP/IP and SMTP-based networks.

A SMTP client will contact the destination host's SMTP server directly to deliver the mail. It will keep the mail item being transmitted until it has been successfully copied to the recipient's SMTP server queue. This is different from the store-and-forward principle that is common in many other electronic mailing systems, in which the mail item may pass through a number of intermediate hosts in the same network on its way to the destination and where successful transmission from the sender only indicates that the mail item has reached the first intermediate hop ("Simple Mail Transfer Protocol" [SMTP] 2004).

The RFC 821 standard defines a client-server protocol. The client SMTP is the one, which initiates the session (that is, the sending SMTP) and the server is the one that responds (the receiving SMTP) to the session request. Because the client SMTP frequently acts as a server for a user-mailing program, however, it is often simpler to refer to the client as the sender-SMTP and to the server as the receiver-SMTP.

An SMTP-based process can transfer electronic mail to another process on the same network or to another network via a relay or gateway process accessible to both networks (Sheldon 2001). An e-mail message may pass through a number of intermediate relay or gateway hosts on its path from a sender to a recipient. A simple model of the components of the SMTP system is shown in Figure 1.

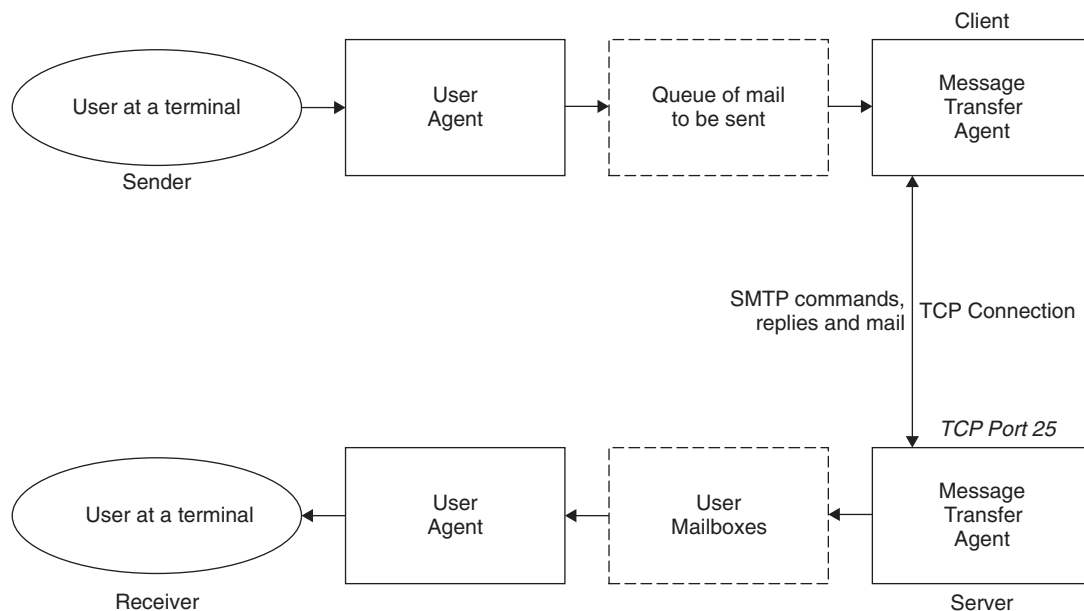

Figure 1: The basic simple mail transfer protocol (SMTP) model

Users deal with a user agent (UA). Popular user agents for UNIX include Berkeley Mail, Elm, MH, Pine, and Mutt. The user agents for Windows include Microsoft Outlook/Outlook Express and Netscape/Mozilla Communicator. The exchange of mail using TCP is performed by an MTA. The most common MTA for UNIX systems is Sendmail, and for Windows is Microsoft Exchange 2000/2003. In addition to stable host-based e-mail servers, Microsoft Corporation has developed LDAP/Active-directory servers and B2B-servers that enhance mail-delivery practices. Users normally do not deal with the MTA. It is the responsibility of the system administrator to set up the local MTA. Users often have a choice, however, for their user agent (Stevens 1993). The MTA maintains a mail queue so that it can schedule repeat delivery attempts in case a remote server is unable. Also the local MTA delivers mail to mailboxes, and the information can be downloaded by the UA (see Figure 1).

The RFC 821 standard specifies the SMTP protocol, which is a mechanism of communication between two MTAs across a single TCP connection. The RFC 822 standard specifies the format of the electronic mail message that is transmitted using the SMTP protocol (RFC 821) between the two MTAs. As a result of a user mail request, the sender-SMTP establishes a two-way connection with a receiver-SMTP. The receiver-SMTP can be either the ultimate destination or an intermediate one (known as a mail gateway). The sender-SMTP will generate commands, which are replied to by the receiver-SMTP (see Figure 1).

Both the SMTP client and server should have two basic components: UA and local MTA. There are few cases of sending electronic-mail messages across networks. In the first case of communication between the sender and the receiver across the network (see Figure 1), the sender's UA prepares the message, creates the envelope, and puts message in the envelope. The MTA transfers the mail across the network to the TCP-port 25 of the receiver's MTA. In the second case of communication between the sending host (client) and the receiving host (server), *relaying* could be involved (see Figure 2). In addition to one MTA at the sender site and one at the receiving site, other MTAs, acting as client or server, can relay the electronic mail across the network.

The most common way in the early days of SMTP was through a process called *relaying* (Kozierok 2006). SMTP routing information was included along with the e-mail address, to specify a sequence of SMTP servers that the mail should be relayed through to get to its destination. The system of relays allows sites that do not use the TCP/IP protocol suite to send electronic mail to users on other sites that may or may not use the TCP/IP protocol suite. This third scenario of communication between the sender and the receiver can be accomplished through the use of an e-mail gateway, which is a relay MTA that can receive electronic mail prepared by a protocol other than SMTP and transform it to the SMTP format before sending it. The e-mail gateway can also receive electronic mail in the SMTP format, change it to another format, and then send it to the MTA of the client that does not use the TCP/IP protocol suite (Forouzan 2005). In various implementations, there is the capability to exchange mail between the

TCP/IP SMTP mailing system and the locally used mailing systems. These applications are called mail gateways or mail bridges. Sending mail through a mail gateway may alter the end-to-end delivery specification, because SMTP will only guarantee delivery to the mail-gateway host, not to the real destination host, which is located beyond the TCP/IP network. When a mail gateway is used, the SMTP end-to-end transmission is host-to-gateway, gateway-to-host or gateway-to-gateway; the behavior beyond the gateway is not defined by SMTP.

The creation of domain name system (DNS) radically changed the e-mail delivery approach. DNS includes support for a special *mail exchanger record* that allows easy mapping from the domain name in an e-mail address to the IP address of the SMTP server that handles mail for that domain (Kozierok 2006). The sending SMTP server uses DNS to find the mail exchanger record of the domain to which the e-mail is addressed. The sender uses this information for identifying the DNS name of the recipient's SMTP server and for resolving an IP address that can be used for a direct connection between the sender's SMTP server and the recipient's one to deliver the e-mail (RFC 2821).

USER AGENT

Introduced in RFC 821 and RFC 822, the SMTP defines user agent functionality, but not the implementation details. A survey of the SMTP implementations can be found in RFC 876. The UA is a program that is used to send and receive electronic mail. The most popular user agent programs for UNIX are Berkeley Mail, Elm, MH, Mutt, Mush, and Zmail. Some UAs have an extra user interface (e.g., Eudora) that allows window-type interactions with the system. The user agents for Windows include Microsoft Outlook/Outlook Express and Netscape/Mozilla Communicator.

Sending E-Mail

Electronic mail is sent by a series of request-response transactions between a client and a server. An SMTP transaction consists of the envelope and message, which is composed of header (with From: and To: fields) and body (text after headers sent with the DATA command). The envelope is transmitted separately from the message itself using MAIL FROM and RCPT TO commands (see RFC 1123). A null line, that is, a line with nothing preceding the <CRLF> sequence, terminates the mail header. Some implementations (e.g., VM, which does not support zero-length records in files), however, may interpret this differently and accept a blank line as a terminator (SMTP 2004). Everything after the null (or blank) line is the message body, which is a sequence of lines containing ASCII characters. The message body contains the actual information that can be read by the recipient.

Mail Header Format

The header includes a number of key words and values that define the sending date, sender's address, where replies should go, and some other information.

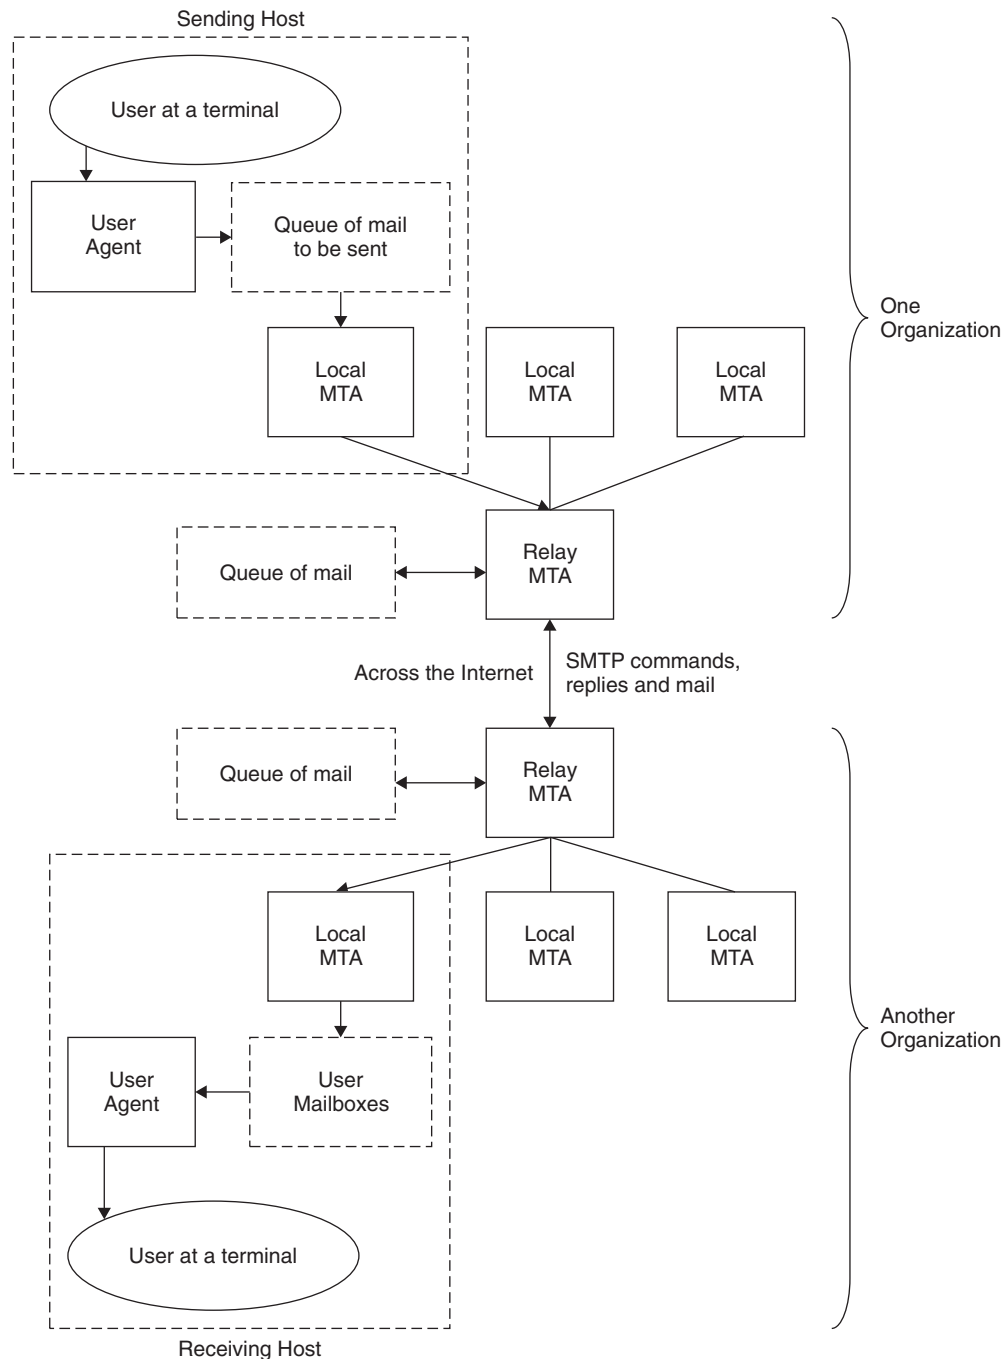

Figure 2: The simple mail transfer protocol (SMTP) model with relay mail transfer agents

The header is a list of lines, of the form (SMTP 2004):

field-name: field-value

Fields begin in column 1: Lines beginning with white space characters (SPACE or TAB) are continuation lines, which are unfolded to create a single line for each field in the canonical representation. Strings enclosed in ASCII quotation marks indicate single tokens within which special characters such as the colon are not significant. Many important field values (such as those for the "To"

and "From" fields) are "mailboxes." The most common forms for these are the following:

- jsmith@mail.it.rivier.edu
- John Smith <jsmith@mail.it.rivier.edu>
- "John Smith" <jsmith@mail.it.rivier.edu>

The string "John Smith" is intended for human recipients and is the name of the mailbox owner. The string "jsmith@mail.it.rivier.edu" is the computer-readable address of the

mailbox (the angle brackets are used to delimit the address but are not part of it). One can see that this form of addressing is closely related to the domain name system (DNS) concept (Internet Assigned Numbers Authority [IANA] 2006). In fact, the client SMTP uses the DNS to determine the IP address of the destination mailbox.

Some frequently used fields (key words) are the following:

- to Primary recipients of the message.
- cc Secondary (“carbon-copy”) recipients of the message.
- from Identity of sender.
- reply-to The mailbox to which responses are to be sent. This field is added by the originator.
- return-path Address and route back to the originator. This field is added by the final transport system that delivers the mail.
- Subject Summary of the message. The user usually provides the summary.

Receiving E-Mail

The UA periodically checks the content of the mailboxes (see Figure 1). It informs the user about mail arrival by giving a special notice. When the user tries to read the mail, a list of arrived mail packages is displayed. Each line of the list contains a brief summary of the information about a particular package in the mailbox. The summary may include the sender mail address, the subject, and the time the mail was received or sent. By selecting any of the packages, the user can view its contents on the terminal display.

The SMTP Destination Address

The SMTP destination address (a mailbox address), in its general form *local-part@domain-name*, can take several forms (SMTP 2004):

- user@host—For a direct destination on the same TCP/IP network.
- user%remote-host@gateway-host—For a user on a non-SMTP destination remote-host, via the mail gateway gateway-host.
- @host-a,@host-b:user@host-c—For a relayed message. This form contains explicit routing information. The message will first be delivered to host-a, who will resend (relay) the message to host-b. Host-b will then forward the message to the real destination host-c. Note that the message is stored on each of the intermediate hosts; therefore, there is no end-to-end delivery in this case. This address form is obsolete and should not be used (see RFC 1123).

Delayed Delivery

The SMTP protocol allows delayed delivery, and the message can be delayed at the sender site, the receiver site, or the intermediate servers (Forouzan 2005).

In the case of delaying at the sender site, the client has to accommodate a spooling system, in which e-mail messages are stored before being sent. A message created by the user agent is delivered to the spool storage. The client mail transfer agent periodically (usually every 10 to 30 minutes) checks the spool to find the mail that can be sent. The mail will be sent only if the receiver is ready and the IP address of the server has been obtained through DNS. If a message cannot be delivered in the timeout period (usually about 3 to 5 days), the mail returns to the sender.

Upon receiving the message, the server-MTA stores it in the mailbox of the receiver (see Figure 1). In this case, the receiver can access the mailbox at any convenient time.

Finally, the SMTP standard procedures allow intermediate MTAs to serve as clients and servers. Both intermediate clients and servers can receive mail, store mail messages in their mailboxes and spools, and send them later to an appropriate destination.

Aliases

The SMTP mechanism allows one name, an alias, to represent several e-mail addresses (this feature is known as “one-to-many alias expansion”; Forouzan 2005). Additionally, a single user can also be defined by several e-mail addresses (this is called “many-to-one alias expansion”). The system can handle these expansions by including an alias expansion facility (connected to the alias databases) at both the sender and receiver sites.

MAIL TRANSFER AGENT (MTA)

MTAs transfer actual mail. The system must have the client MTA for sending e-mail and the server MTA for receiving mail (see Figure 1). The SMTP-related RFCs do not define a specific MTA. The UNIX-based MTA uses commonly the Sendmail utility. The most common MTA for Windows is Microsoft Exchange 2000/2003.

The “mta-name-type” and “address-type” parameters (e.g., dnc and rfc822 for the Internet mail, respectively) are defined for use in the SMTP delivery status notification document (see RFC1891). An identification of other mail systems can also be used. One of the identification methods has been described in “The COSINE and Internet X.500 Schema” (section 9.3.18) in the RFC1274 document. The mail system names listed here are used as the legal values in that schema under the “otherMailbox” attribute “mailboxType” type, which must be a PrintableString. The “Mapping between X.400 (1988)/ISO 10021 and RFC 822” is described in the section 4.2.2 of the RFC1327 document. The names listed here are used as the legal values in that schema under the “std-or-address” attribute “registered-dd-type” type, which must be a “key-string” (for details, see Mail Parameters 2006).

SMTP Mail Transaction Flow

The SMTP protocol (RFC 821) defines how commands and responses must be sent by the MTAs. The client sends commands to the server, and the server responds with numeric reply codes and optional human-readable strings.

There are a small number of commands (less than a dozen) that the client can send to the server. An example of sending a simple one-line message and an interpretation of the SMTP connection can be found in Stevens (1993).

Although mail commands and replies are rigidly defined (see “SMTP Commands” and “SMTP Responses” later in this chapter), the exchange can easily be followed in Figure 3.

In this scenario (Comer 2005; SMTP 2004), the user jsmith at host sun.it.rivier.edu sends a note to users darien, steve and bryan at host mail.unh.edu. Here the lines sent by the server (receiver) are preceded by S, and the lines sent by the client (sender) preceded by C. Note that the message header is part of the data being transmitted. All exchanged messages (commands, replies, and data) are text lines, delimited by a <CRLF>. All replies have a numeric code at the beginning of the line.

The scenario includes the following steps (SMTP 2004):

1. The client (sender-SMTP) establishes a TCP connection with the destination SMTP and then waits for the server to send a 220 Service ready message or a 421 Service not available message when the destination is temporarily unable to proceed.
2. The HELO command is sent, and the receiver is forced to identify himself by sending back its domain name. The client (sender-SMTP) can use this information to verify if it contacted the right destination SMTP. If the
3. The client (sender) now initiates the start of a mail transaction by sending a MAIL command to the receiver. This command contains the reverse-path, which can be used to report errors. Note that a path can be more than just the *user-mailbox@host-domain-name* pair. In addition, it can contain a list of routing hosts. Examples of this are when the mail passes a mail bridge or when the user provides explicit routing information in the destination address. If accepted, the server (receiver) replies with a 250 OK message.
4. The second step of the actual mail exchange consists of providing the server SMTP with the destinations for the message (there can be more than one recipient). This is done by sending one or more RCPT TO:<forward-path> commands. Each of them will receive a 250 OK reply if the destination is known to the server or a 550 No such user here reply if it is not.

```

Figure 3: An example of the interactive session between the client (“sender” C) and the server (“receiver” S)

5. When all RCPT commands are sent, the client (sender) issues a DATA command to notify the server (receiver) that the message contents are following. The server replies with the 354 Start mail input, end with <CRLF>.<CRLF> message.
6. The client now sends the data line by line, ending with the sequence <CRLF>.<CRLF> line on which the receiver acknowledges with a 250 OK or an appropriate error message if anything went wrong.
7. The following actions (SMTP 2004) are possible after that:
 - The sender has no more messages to send; he will end the connection with a QUIT command, which will be answered with a 221 Service closing transmission channel reply (see Figure 3).
 - The client (sender) has another message to send and simply goes back to step 3 to send a new MAIL command.

In this description, only the most important commands that must be recognized in each SMTP implementation (see RFC821) have been mentioned. Other optional commands (the RFC 821 standard does not require them to be implemented everywhere) implement several important functions such as forwarding, relaying, mailing lists, and so on.

SMTP Commands

The commands formed with ASCII (text) are sent from the client to the server. The simple structure of the commands allows for building mail clients and servers on any platform. Table 1 lists commands and their description and formats. The command consists of a key word followed by zero or more arguments. Five commands (HELO, MAIL FROM, RCPT TO, DATA, and QUIT) are mandatory, and every implementation must support them. The EHLO command is strongly preferred to HELO when the server will accept the former (RFC 2821). Servers must continue to accept and process HELO in order to support older clients.

The other two commands (RSET and NOOP) are often used and highly recommended. The VRFY and EXPN commands are often disabled. This technique allows reducing spam validation of email addresses. The next five programs (TURN, HELP, SEND FROM, SOML FROM, and SAML FROM) are seldom used. The TURN command raises security issues (RFC 2821), because, in the absence of strong authentication of the host requesting that the client and server switch roles, it can easily be used to divert mail from its correct destination. SMTP systems should not use this command unless the server can authenticate the client. The SEND, SAML, and SOML commands were originally introduced in RFC 821 to provide additional, optional mechanism of delivering messages directly to the user's terminal screen. They were rarely implemented, and changes in workstation technology and the introduction of other protocols may have rendered them obsolete even where they are implemented (RFC 2821). SMTP clients should not provide SEND, SAML, or SOML as services.

For a full list of commands, see the RFC 821 "Simple Mail Transfer Protocol," RFC 1123 "Requirements for

Internet Hosts—Application and Support," and RFC 2821 "Simple Mail Transfer Protocol." For details of SMTP service extensions, see the RFC 1651 "SMTP Service Extensions," RFC 1652 "SMTP Service Extension for 8bit-MIMEtransport," RFC 1653 "SMTP Service Extension for Message Size Declaration," and RFC 2554 "SMTP Service Extension for Authentication."

The commands normally progress in a sequence (one at a time). The advanced pipelining feature introduced in the RFC 2920 document allows multiple commands to be sent to a server in a single operation of the TCP-send type.

Mail Service Types

The set of services desired from a mail server are sometimes characterized by the "hello" key word. The various mail service types are as follows (Mail Parameters 2006):

- HELO for Simple Mail (see RFC821)
- EHLO for Mail Service Extensions (see RFC1869)
- LHLO for Local Mail (see RFC2033).

The EHLO key word has a numerical parameter SIZE for specifying the new format of e-mail messages (see RFC1870).

SMTP Service Extensions

SMTP (RFC821) specifies a set of commands or services for mail transfer. A general procedure for extending the set of services is defined in the STD11/RFC1869 document. The service extensions are identified by key words sent from the server to the client in response to the EHLO command (Mail Parameters 2006). The set of service extensions are as follows:

- SEND—Send as mail (see RFC821)
- SOML—Send as mail or to terminal (see RFC821)
- SAML—Send as mail and to terminal (see RFC821)
- EXPN—Expand the mailing list (see RFC821)
- HELP—Supply helpful information (see RFC821)
- TURN—Turn the operation around (see RFC821)
- 8BITMIME—Use 8-bit data; it defines support for the 8-bit content transfer encoding type in MIME (see RFC1652)
- AUTH—Use to implement an authorization mechanism for servers requiring enhanced security (see RFC2554)
- SIZE—Message size declaration, which allows information about the size of a message to be declared by an SMTP sender prior to transmitting it, so the SMTP receiver can decide if it wants the message or not (see RFC1870)
- CHUNKING—Chunking (see RFC3030)
- BINARYMIME—Binary MIME (see RFC3030)
- CHECKPOINT—Checkpoint/restart (see RFC1845)
- PIPELINING—Command pipelining, which allows multiple commands to be transmitted in batches from the SMTP sender to the receiver, rather than sending

Table 1: Simple Mail Transfer Protocol (SMTP) Commands. Adapted from SMTP Specifications 2006.

Command	Description	Format	References
ATRN	Authenticated TURN		RFC 2645
AUTH	Authentication		RFC 2554
BDAT	Binary data		RFC 3030
DATA	Data; used to send the actual message; all lines that follow the DATA command are treated as the e-mail message; the message is terminated by a line containing just a period	DATA Best wishes.	RFC 821, RFC 2821
EHLO	Extended Hello		RFC 1869, RFC 2821
ETRN	Extended TURN		RFC 1985
EXPN	Expand; asks the receiving host to expand the mailing list sent as the arguments and to return the mailbox addresses of the recipients that comprise the list	EXPN: a b c	RFC 821, RFC 2821
HELO	Hello; used by the client to identify itself	HELO: sun.it.rivier.edu	RFC 821, RFC 2821
HELP	Help; requests the recipient to send information about the command sent as the argument	HELP: mail	RFC 821, RFC 2821
MAIL FROM	Mail; used by the client to identify the sender of the message; the argument is the e-mail address of the sender	MAIL FROM: jsmith@sun.it.rivier.edu	RFC 821, RFC 2821
NOOP	No operation; used by the client to check the status of the recipient; requires an answer from the recipient	NOOP	RFC 821, RFC 2821
QUIT	Quit; terminates the message	QUIT	RFC 821, RFC 2821
RCPT	Recipient; used by the client to identify the intended recipient of the message; if there are multiple recipients, the command is repeated	RCPT TO: steve@unh.edu	RFC 821, RFC 2821
RSET	Reset; aborts the current e-mail transaction; the stored information about the sender and recipient is deleted; the connection will be reset	RSET	RFC 821, RFC 2821
SAML	Send to the mailbox or terminal; specifies that the mail have to be delivered to the terminal or the mailbox of the recipient; the argument is the address of the sender	SAML FROM: jsmith@sun.it.rivier.edu	RFC 821
SEND	Send; specifies that the mail is to be delivered to the terminal of the recipient and not the mailbox; if the recipient is not logged in, the mail is bounced back; the argument is the address of the sender	SEND FROM: jsmith@sun.it.rivier.edu	RFC 821
SOML	Send to the mailbox or terminal; it specifies that the mail is to be delivered to the terminal or the mailbox of the recipient; the argument is the address of the sender	SOML FROM: jsmith@sun.it.rivier.edu	RFC 821
STARTTLS	Extended Hello with transport layer security		RFC 3207
TURN	Turn; it lets the sender and the recipient switch positions whereby the sender becomes the recipient and vice versa (most SMTP implementations today do not support this feature; see RFC2821)	TURN	RFC 821
VRFY	Verify; it verifies the address of the recipient, which is sent as the argument; the sender can request the receiver to confirm that a name identifies a valid recipient	VRFY: steve@unh.edu	RFC 821, RFC 2821

one command at a time and waiting for a response code (see RFC2920)

- DSN—Delivery status notification, which allows an SMTP sender to request that the SMTP receiver notify if a problem occurs in delivering a message the sender gives to it (see RFC1891)
- ETRN—Extended turn (see RFC1985)
- ENHANCEDSTATUSCODES—Enhanced status codes; it extends the traditional 3-digit SMTP reply code format with extra codes that provide more information (see RFC2034 and RFC1893)
- STARTTLS—Start TLS (see RFC3207)

Some of these key words have parameters (for details, see Mail Parameters 2006).

SMTP Responses

Responses are sent from the server to the client. A response is a three-digit code that may be followed by additional textual information. The meanings of the first digit are as follows:

- 2bc—positive completion reply; the requested command has been successfully completed and a new command can be started.
- 3bc—positive intermediate reply; the requested command has been accepted, but the server needs some more information before completion can occur.
- 4ab—transient negative completion reply; the requested command has been rejected, but the error condition is temporary, and the command can be sent again.
- 5ab—permanent negative completion reply; the requested command has been rejected, and the command cannot be sent again (e.g., see RFC 1846).

The second (b) and the third (c) digits provide further details about the responses. Table 2 shows the list of typical reply codes and their descriptions.

SMTP SERVER

The SMTP server sends and receives mail from other Internet hosts using the SMTP. The SMTP server processes all incoming and outgoing mail. Outgoing mail is spooled until the SMTP server can confirm it has arrived at its destination; incoming mail is spooled until users access it by using a POP3 or IMAP4 mail client. Spooling allows the transfer from client and server to occur in the background. The instructions on how to configure the SMTP server in the Windows NT environment and how to set options to provide security for the SMTP server are described in “How to Set SMTP Security Options” (2006).

ON-DEMAND MAIL RELAY

On-demand mail relay (ODMR), also known as authenticated TURN (ATRN), is an e-mail service that allows a user to connect to an Internet service provider (ISP), authenticate, and request e-mail using a dynamic IP address (instead of static IP addresses used in a “traditional” SMTP

model) from any Internet connection (see RFC 2645). The initial client and server roles are short-lived, because the point is to allow the intermittently connected host to request mail held for it by a service provider. The customer initiates a connection to the provider, authenticates, and requests its mail. The roles of client and server then reverse, and the normal SMTP scenario proceeds. The provider has an ODMR process listening for connections on the ODMR port 366 (SMTP Specifications 2006). On the server, this process implements the EHLO, AUTH, ATRN, and QUIT commands. Also, it has to be an SMTP client with access to the outgoing mail queues. An MTA normally has a mail client component, which processes the outgoing mail queues, attempting to send mail for particular domains, based on time or events, such as new mail being placed in the queue or receipt of an ETRN command by the SMTP server component. The ODMR service processes the outgoing queue on request. The ISP provider side has normal SMTP server responsibilities, including generation of delivery failure notices (SMTP Specifications 2006).

MULTIPURPOSE INTERNET MAIL EXTENSIONS (MIME)

The RFC 821/ STD 10 standard specifies that data sent via SMTP is 7-bit ASCII data, with the high-order bit cleared to zero. This is adequate in most instances for the transmission of English text messages but is inadequate for non-English text or nontextual data.

There are two approaches to overcoming these limitations. In the first approach, the multipurpose Internet mail extensions (MIME) supplementary protocol was defined in RFC 1521 and RFC 1522, which specify a mechanism for encoding text and binary data as 7-bit ASCII within the mail envelope defined by the RFC 822 standard. MIME is also described in SMTP (2006).

In the second approach, the SMTP service extensions (RFC 1651, RFC 1652, and RFC 1653) define a mechanism to extend the capabilities of SMTP beyond the limitations imposed by the RFC 821 standard. The RFC 1651 document introduces a standard for a receiver-SMTP to inform a sender-SMTP, which service extensions it supports. New procedures modifies the RFC 821 standard to allow a client SMTP agent to request that the server responds with a list of the service extensions that it supports at the start of an SMTP session. If the server SMTP does not support the RFC 1651, it will respond with an error and the client may either terminate the session or attempt to start a session according to the rules of the RFC 821 standard. If the server does support the RFC 1651, it may also respond with a list of the service extensions that it supports. A registry of services is maintained by the Internet Assigned Numbers Authority (IANA 2006); the initial list defined in the RFC 1651 document contains those commands listed in RFC 1123 as optional for SMTP servers.

Specific extensions are defined in RFC 1652 and RFC 1653. A protocol for 8-bit text transmission (RFC 1652) allows an SMTP server to indicate that it can accept data consisting of 8-bit bytes. A server, which reports that this

Table 2: Simple Mail Transfer Protocol (SMTP) Reply Codes. Adapted from SMTP Specifications 2006.

Code	Description
Positive Completion Reply	
211	System status or system help reply
214	Help message
220	<i>Domain</i> service ready; ready to start TLS
221	<i>Domain</i> service closing transmission channel
250	OK, queuing for node <i>node</i> started; requested command completed
251	OK, no messages waiting for node <i>node</i> ; user not local, will forward to <i>forwardpath</i>
252	OK, pending messages for node <i>node</i> started; cannot VRFY user (e.g., information is not local) but will take message for this user and attempt delivery
253	OK, <i>messages</i> pending messages for node <i>node</i> started
Positive Intermediate Reply	
354	Start mail input; end with <CRLF>.<CRLF>
355	Octet-offset is the transaction offset
Transient Negative Completion Reply	
421	<i>Domain</i> service not available, closing transmission channel
432	A password transition is needed
450	Requested mail action not taken: mailbox unavailable; ATRN request refused
451	Requested action aborted: local error in processing; unable to process ATRN request now
452	Requested action not taken: insufficient system storage
453	You have no mail
454	TLS not available due to temporary reason; encryption required for requested authentication mechanism
458	Unable to queue messages for node <i>node</i>
459	Node <i>node</i> not allowed: <i>reason</i>
Permanent Negative Completion Reply	
500	Command not recognized: <i>command</i> ; Syntax error
501	Syntax error in parameters or arguments; no parameters allowed
502	Command not implemented
503	Bad sequence of commands
504	Command parameter temporarily not implemented
521	<i>Machine</i> does not accept mail
530	Must issue a STARTTLS command first; encryption required for requested authentication mechanism
534	Authentication mechanism is too weak
538	Encryption required for requested authentication mechanism
550	Requested action not taken (command is not executed): mailbox unavailable
551	User not local; please try <i>forwardpath</i>
552	Requested mail action aborted: exceeded storage allocation
553	Requested action not taken: mailbox name not allowed
554	Transaction failed

extension is available to a client, must leave the high-order bit of bytes received in an SMTP message unchanged if requested to do so by the client.

The MIME and SMTP service extension approaches are complementary. Following their procedures (RFC 1652), nontraditional SMTP agents can transmit messages, which are declared as consisting of 8-bit data rather than 7-bit data, when both the client and the server conform to the RFC 1651 or RFC 1652 options (or both). Whenever a client SMTP attempts to send 8-bit data to a server, which does not support this extension, the client SMTP must either encode the message contents into a 7-bit representation compliant with the MIME standard or return a permanent error to the user.

The SMTP service extension has the limitation on maximum length of a line (only up to 1,000 characters as required by the RFC 821 standard). The service extension also limits the use of non-ASCII characters to message headers, which are prohibited by the RFC 822 regulations.

The RFC 1653 document introduces the protocol for message size declaration that allows a server to inform a client of the maximum size message it can accept. If both server and client support the message size declaration extension, the client may declare an estimated size of the message to be transferred, and the server will return an error if the message is too large. Each of these SMTP service extensions is a draft standard protocol and each has a status of elective.

The MIME can be considered as a set of software functions that transforms non-ASCII data to ASCII characters and vice versa, as shown in Figure 4.

The MIME protocols define five header lines that can be added to the original header section to define the transformation parameters: MIME-version, content-type, content-transfer-encoding, content-id, and content-description (see Figure 5). Each header line is described in detail in the following sections.

MIME-Version

The header line MIME-Version: 1.1 declares that the message was composed using the (current) version 1.1 of the MIME protocol.

Content-Type

The header line Content-Type:<type/subtype; parameters> defines the type of data used in the body of the message. The identifiers of the content type and the content subtype are separated by a slash. Depending on the subtype, the header may contain other parameters. The MIME standard allows seven basic content types of data, the valid subtypes for each, and transfer encodings, which are listed in Table 3. Examples of the content-type headers can be found in Forouzan (2005).

Content-Transfer-Encoding

The Content-Transfer-Encoding:<type> header line defines the method to encode the messages into a bit-stream

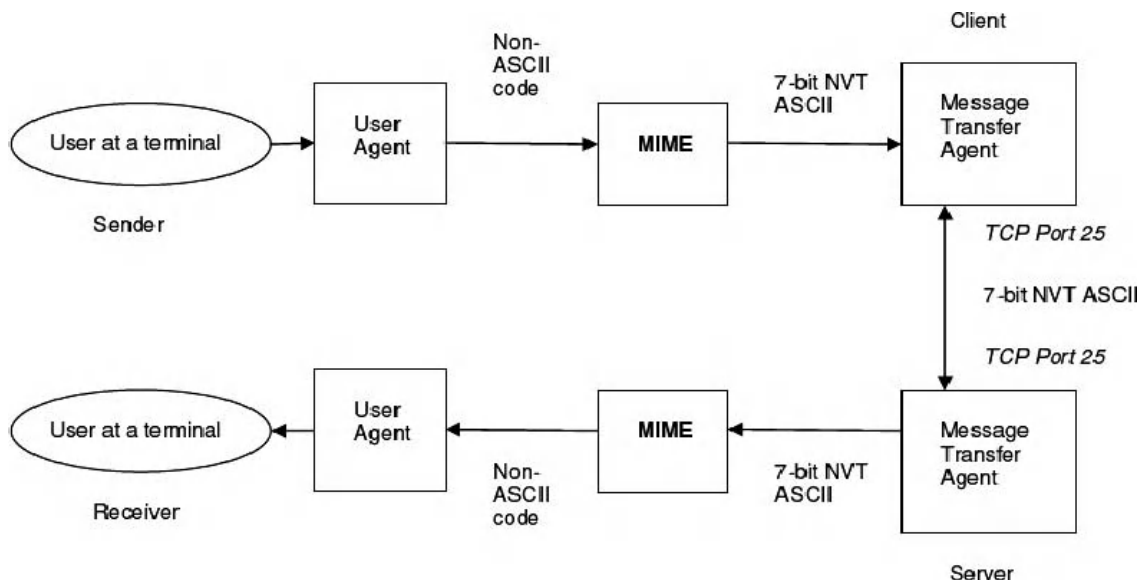

Figure 4: MIME functionality

Figure 5: MIME header

Table 3: Data Types and Subtypes in a Multipurpose Internet Mail Extensions (MIME) Content-Type Header Declaration.

Type	Subtype	Description
Text	Plain	Unformatted 7-bit ASCII text; no transformation by MIME is needed
	HTML	HTML format
Multipart	Mixed	Body contains ordered parts of different data types
	Parallel	Body contains no-ordered parts of different data types
	Digest	Body contains ordered parts of different data types, but the default is message/RFC822
	Alternative	Parts are different versions of the same message
Message	RFC822	Body is an encapsulated message
	Partial	Body is a fragment of a bigger message
	External-Body	Body is a reference to another message
Image	JPEG	Image is in JPEG format
	GIF	Image is in GIF format
Video	MPEG	Video is in MPEG format
Audio	Basic	Single channel encoding of voice at 8 KHz
Application	PostScript	Adobe PostScript
	Octet-stream	General binary data (eight-bit bytes)

GIF = Graphics Interchange Format; HTML = Hypertext Markup Language; JPEG = Joint Photographic Experts Group; MPEG = Motion Picture Experts Group.

of 0s and 1s for transport. The five types of encoding are as follows:

- 7bit—for NVT ASCII characters and short lines of less than 1,000 characters.
- 8bit—for non-ASCII characters and short lines of less than 1,000 characters; the underlying SMTP protocol must be able to transfer 8-bit non-ASCII characters (this type is not recommended).
- binary—for non-ASCII characters with unlimited-length lines; this is 8-bit encoding. The underlying SMTP protocol must be able to transfer 8-bit non-ASCII characters (this type is not recommended).
- base64—for sending data made of bytes when the highest bit is not necessarily zero; 6-bit blocks of data are encoded into 8-bit printable ASCII characters (for details, see Tschabitscher 2006; Stevens 1993), which can then be sent as any type of character set supported by the underlying mail transfer mechanism.
- quoted-printable—for sending data that consist of mostly ASCII characters with a small non-ASCII portion; if a character is not ASCII, it is sent as three characters: the first character is the equal sign, and the next two are the hexadecimal representation of the byte.

Although the content type and encoding are independent, the RFC 1521 document recommends quoted-printable for text with non-ASCII data, and base64 for image, audio, video, and octet-stream application data. This allows maximum interoperability with RFC 821 conformant MTAs (Stevens, 1993).

Figure 6 shows an example of a multi-part message in MIME format with mixed subtypes.

Content-Id

The header line Content-Id: id=<content-id> uniquely identifies the whole message in a multiple message environment.

Content-Description

The header line Content-Description:<description> defines whether the body is image, audio, or video.

Security Scheme for MIME

The S/MIME is a security scheme for the MIME protocol. It was developed by RSA Security and is an alternative to the pretty good privacy (PGP) encryption and digital signature scheme that uses public-key cryptography. The S/MIME scheme was standardized by IETF. According to “Report of the IAB Security Architecture Workshop” (RFC 2316), the designated security mechanism for adding secured sections to MIME-encapsulated e-mail is security/multipart, as described in “Security Multiparts for MIME: Multipart/Signed and Multipart/Encrypted” (RFC 1847).

The S/MIME is widely used by large companies that need to standardize e-mail security for both interorganization and intraorganization mail exchange (Internet Engineering Task Force [IETF] SMIME, 2006). It requires establishing a public-key infrastructure either in-house or by using any of the public certificate authorities (Sheldon 2001).

Figure 6: An example of a multi-part message in MIME format with mixed subtypes

MAIL TRANSMISSION TYPES

The SMTP (RFC821) and the Standard for the Format of Advanced Research Project Agency (ARPA) Internet Text Messages (RFC822) specify that a set of “Received” lines will be prepended to the headers of electronic mail messages as they are transported through the Internet (Mail Parameters 2006). The received line may optionally include either or both a “via” phrase or a “with” phrase (or both). The legal value for the “via” phrase is intended to indicate the link or physical medium over which the message was transferred (e.g., the UUCP link type should be specified for the Unix-to-Unix Copy Program). The “with” phrase is intended to indicate the protocol or logical process that has been used to transfer the message (e.g., SMTP or ESMTP parameters are used respectively for SMTP [RFC821] or SMTP with service extensions [RFC1869] protocol types).

MAIL ACCESS MODES

To reach its final destination, an e-mail message should be handled by a mail server, the mail access protocol, and the mail client. A general concept of how these components work together is described in “Accessing Your Mail” (QUALCOMM 1997).

An Internet mail server (known as the mail transfer agent, described earlier) is the software responsible for transmitting and receiving e-mail across the Internet. The MTA software is run on a computer that has a connection to the Internet and is managed, monitored, and backed up by ISPs or a company’s information services staff. Some mail servers store mail only until the user retrieves it, whereas others store user mail permanently. An e-mail user typically uses a mail client program to interact with the mail server (Rose 1993).

A mail client (known as the mail user agent, described earlier) is the software that a user employs to read, send, file, and otherwise process the electronic mail. Usually running on a user’s desktop computer, the mail client also manages related e-mail data (address books, spelling dictionaries, and stationery). The mail client connects to a mail server to retrieve new mail. Some mail clients also use the mail server to store all e-mail (Rose 1993).

The communication between the mail client and mail server is regulated by the mail access protocol, a standardized set of transmitted commands and responses sent over many different types of network connections. The protocol commands (created for managing access to the Internet e-mail only) depend on a design approach that can significantly affect the manner, modes, characteristics,

and capabilities of the interaction between the mail client and mail server (QUALCOMM 1997). The SMTP protocol handles the task of the actual sending of e-mail on the Internet.

A mail access protocol operates in three common modes that differ in where and how a user stores and processes his or her mail (QUALCOMM 1997):

- **Offline mode**—e-mail is downloaded from a temporary storage on the mail server to the user's computer. After download, the mail is deleted from the server.
- **Online mode**—user's e-mail, his or her inbox, and all filed mail remains permanently on the mail server. By connecting to the server and establishing an e-mail session, the user can download a temporary copy of his or her e-mail and read it, or send e-mail. Once the connection is finished, the copy is erased from user's computer, and only the original remains on the server.
- **Disconnected/resynchronization mode**—combines both offline and online modes. A copy of the user's e-mail is downloaded to his or her computer(s), and the original message remains on the mail server. The user can change a local copy of his or her e-mail on any computer, then resynchronize all copies, including the original e-mail message on the server and copies on additional computers.

All three modes offer multiplatform support. This includes support for existing platforms such as UNIX, Microsoft Windows, and Apple Macintosh, and future platforms such as Java Mail Service-based network computers. All three modes, including their advantages and disadvantages, are discussed in detail in "Accessing Your Mail" (QUALCOMM 1997). Two dedicated protocols (POP3 and IMAP4) of retrieving e-mail are considered in the next section.

Instead of using POP3 or IMAP4, on some systems it is possible for a user to have direct server access to e-mail. This is most commonly done on UNIX systems, where protocols like TELNET or NFS (Network File System) can give a user shared access to mailboxes on a server (TCP/IP Guide 2006). Being the oldest method of e-mail access, it provides the user (who must be on the Internet to read e-mail) with the most control over his or her mailbox, and is well-suited to those who must access mail from many locations.

MAIL ACCESS PROTOCOLS

POP3

POP is used on the Internet to retrieve e-mail from a mail server. There are two versions of POP. The first, known as POP2 (RFC 937), became a standard in the mid-1980s and requires SMTP to send messages. Nowadays it has a status of "not recommended." The newer version, POP3 (RFC 1725), can be used with or without SMTP.

POP was designed primarily to support the offline access mode (RFC 1939). Typically, e-mail arrives from the network and is placed in the user's inbox on the server. POP is then used to transfer the mail from the user's inbox on the server to the user's computer. POP is designed so that mail client software can determine which messages

have been previously downloaded from the server. The mail client can then download only new messages. POP also provides the ability to selectively delete messages from the server. It can be used by a mail client to perform basic resynchronization of the inbox on the server and on the user's computers. The client can leave the most recent messages on the server after they have been downloaded. These messages can then be downloaded a second time to a second computer. Additionally, some POP implementations provide optional features, such as allowing users to download only headers at one session, to review the topics, and then download selected bodies and attachments in a subsequent session to minimize connection times over slow links (QUALCOMM 1997).

POP servers are widely available both commercially and as freeware on a number of operating systems. Moreover, there are almost no interoperability issues between POP servers and mail clients, and users can use any POP mail client with any POP server. All ISPs support and use POP.

In the end-to-end application related to SMTP, the server must be available whenever a client (sender) transmits mail. If the SMTP server resides on an end-user PC or workstation, that computer must be running the server when the client is trying to send mail. For some operating systems (e.g., when a server program is activated on the VM SMTP service virtual machine or the MAIL program on DOS), the server becomes unavailable and unreachable by the SMTP client (SMTP, 2004). The mail-sending process will fail in these cases. Especially, it is important for single-user systems that the client has an accessible mailbox on various types of server (RFC 1725).

One of the simplest approaches to resolve this problem is to allow the end user to run a client program, which communicates with a server program on a host. This server program acts as both a sender and a receiver SMTP (SMTP 2004). Here the end-user mailbox resides on the server, and the server system is capable of sending mail to other users.

In another approach, the SMTP server function has to be off-loaded from the end-user workstation, but not the SMTP client function. In this case, the user has a mailbox that resides on a server system, and he can send mail directly from the workstation. To collect mail from the mailbox, the user must connect to the mail server system.

The current post office protocol version 3 (RFC 1725) is a draft standard protocol, and its status is elective. POP3 extensions are described in RFC 2449. POP3 security options are introduced in RFC 2595. The RFC 1734 describes the optional AUTH command for indicating an authentication mechanism to the POP3 server, performing an authentication protocol exchange, and optionally negotiating a protection mechanism for subsequent protocol interactions (Sheldon 2001).

IMAP4

IMAP is a protocol for retrieving e-mail messages (RFC 1064). The IMAP4 version is similar to POP3 but supports some additional features. For example, with IMAP4, the user can search through his or her e-mail messages for key words while the messages are still on the mail server.

The user can then choose which messages to download to his or her machine.

IMAP uses SMTP as its transport mechanism. Following the simple analogy (Sheldon, 2001), IMAP servers are like post offices, whereas SMTP is like the postal carriers. IMAP uses TCP to take advantage of its reliable data delivery services, which are allocated on the TCP port 143. The latest IMAP version 4, revision 1 (IMAP4rev1) is defined in RFC 2060.

IMAP has many advanced features, such as the ability to address mail not by arrival number, but by using attributes (e.g., "Download the latest message from Smith"). This feature allows the mailbox to be structured more like a relational database system rather than a sequence of messages (Tanenbaum, 2003). Authentication mechanisms are described in RFC 1731. Security issues have been introduced in "IMAP4/POP Authorization for Simple Challenge/Response" (RFC 2195), "IMAP4 Login Referentials" (RFC 2221), and "IMAP4 Implementation and Best Practices" (RFC 2683).

SMTP VULNERABILITIES

The processes of retrieving e-mail from servers and managing data communication through the Internet are vulnerable to various attacks. A review of vulnerabilities can be found in "Vulnerability Tutorials" (2006) released by the Saint Corporation. The Common Vulnerabilities and Exposures (CVE) organization provides a list of standardized names for SMTP vulnerabilities (for both CVE entries and CAN candidates) and other information security exposures (CVE 2006). Summaries of major SMTP vulnerability problems are discussed in (Riabov 2006).

SMTP was designed in an era when security of the Internet was not an issue. As a result, the SMTP protocol includes no robust security mechanism. For example, someone can use the TELNET protocol to connect directly to an SMTP server on port 25. The SMTP commands and replies can all be sent as text, and, therefore, a person can manually perform a mail transaction. This is useful for debugging, but also makes abuse of a wide open SMTP server trivially easy. Since spammers often do not want to be identified, they employ spoofing techniques to make it more difficult to identify them (Kozierok 2006). Nowadays, most modern SMTP servers incorporate several security features to avoid vulnerability problems.

A security audit of selected SMTP problems has been provided by the U.S. Computer Emergency Readiness Team (CERT) Coordination Center operated by Carnegie Mellon University, and E-Soft. Detailed information about vulnerability problems, possible actions of an attacker or spammer, recommendations for downloading updated versions of software, examples of code modification, and test results can be found on the CERT (2006) and Security Space ("SMTP Problems," 2006) Web sites.

The vulnerability problems can be grouped into several general high-risk categories: buffer overflow; redirection attacks through the firewall; bounced "piping" attacks; and host-shell-gaining attacks. The medium-to-high risk category includes denial-of-service attacks. Low-to-medium-risk categories include mail relaying on the remote SMTP server, mail-queue manipulation

attacks; debug-mode-leak category; and crashing antivirus-software attack ("SMTP Problems" 2006). Most SMTP-specific vulnerabilities occur from misapplied or unapplied patches related to Sendmail installations or misconfigured Sendmail daemons on the SMTP servers (Campbell et al. 2003).

ISPs restrict access to their outgoing mail servers to provide better service to their customers and prevent spam from being sent through their mail servers. There are several methods for establishing restrictions that could result in denying users' access to their outgoing mail server.

Originally (see RFC 821), e-mail servers (configured for SMTP relay) did not verify the claimed sender identity and would simply pass the mail on with whatever return address was specified. Bulk mailers have taken advantage of this to send huge volumes of mail with bogus return addresses. This results in slowing down servers.

To fix the problem, the origin of a spam e-mail should be identified. An e-mail message typically transports through a set of SMTP servers (including the sender's and receiver's servers) before reaching the destination host. Along this pass, messages get "stamped" by the intermediate SMTP servers. The stamps release tracking information that can be identified in the mail headers. Mismatches between the IP addresses and the domain names in the header could unveil the real source of spam mail. The real domain names that correspond to the indicated IP addresses can be found out by executing a reverse DNS lookup. Modern mail programs have incorporated this functionality, which generates a Received: header line that includes the identity of the attacker (see examples in Campbell et al. 2003).

Antispoofing measures are under active development. Mail Abuse Prevention System (MAPS) and Open Relay Behavior-Modification System (ORBS) provide testing, reporting and cataloging of e-mail servers configured for SMTP relay. These organizations maintain real-time blackhole lists (RBL) of mail servers with problematic histories. For protection and security purposes, companies may configure their SMTP servers and other e-mail service systems in such manner that any mail coming from RBL-blacklisted mail servers is automatically rejected (Campbell et al. 2003). Other initiatives for restricting the sender address spoofing include SPF, Hotmail domain cookies, and Microsoft's caller ID. The analysis of various SMTP security issues can be found in (Riabov 2006).

STANDARDS, ORGANIZATIONS, AND ASSOCIATIONS

Internet Assigned Numbers Authority

The IANA (2006) provides the central coordinating functions of the global Internet for the public needs. The IANA organization maintains a registry of the following services:

- Domain name services
- Database of indexes by Top-Level Domains code
- "Whois" service of domain name recognition
- IP address assignment services (for both IPv4 and IPv6)
- Protocol number assignment services

Internet Engineering Task Force Working Groups

Internet electronic mail was originally defined in the RFC821 standard as a part of the IETF project. Since August 1982, e-mail standards declared in this document were updated and revised by the IETF Detailed Revision/Update of Message Standards (DRUMS) Working Group. The group is also searching new directions in the electronic message communication through the Internet. The latest SMTP documents (including RFCs) can be found on the DRUMS Web site (IETF DRUMS 2006).

The IETF Message Tracking Protocol (MSGTRK) Working Group (IETF MSGTRK 2006) is designing diagnostic protocols that a sender can use to request information from servers about the submission, transport, and delivery of a message, regardless of its status. The "Deliver by SMTP Service Extension" document (RFC 2852) specifies extensions to define message delivery time for making a decision to drop the message if it is not delivered within a specific time period. For diagnostic purposes, the "diagnostic-type" parameter (e.g., smtp for the Internet Mail) is defined for use in the SMTP delivery status notification (see RFC1891).

The IETF S/MIME Mail Security (SMIME) Working Group is developing S/MIME security standards. The latest S/MIME documents (including RFCs) can be found on the SMIME Web site (IETF SMIME, 2006).

Internet Mail Consortium

The Internet Mail Consortium Web site (IMC 2006) publishes a complete list of electronic mail-related requests for comments documents (RFCs).

Mitre Corporation

The Mitre Corporation publishes a list of standardized names for all publicly known vulnerabilities and security exposures known as Common Vulnerabilities and Exposures (CVE 2006).

CONCLUSION

SMTP is an application protocol from the TCP/IP protocol suite that enables the support of e-mail on the Internet. Mail is sent by a series of request-response transactions between a client and a server. The transactions pass the message, which is composed of header and body, and the envelope (SMTP source and destination addresses). The header contains the mail address(es), which consists of two parts: a local address (also known as a "user mailbox") and a domain name. Both SMTP client and SMTP server require a user agent (UA) and a mail transfer agent (MTA). The MTA function is transferring the mail across the Internet. The command-response mechanism is used by SMTP to transfer messages between an MTA client and an MTA server in three stages: connection establishment, mail transfer, and connection termination. The envelope is transmitted separately from the message itself using the MAIL and RCPT commands. MIME, which is an extension of SMTP, allows the transfer of non-ASCII

(multimedia) messages. POP3 and the IMAP 4 together with SMTP are used to receive mail by a mail server and hold it for hosts. The SMTP's lack of security is a problem for businesses. The security in the SMTP transactions can be supported by S/MIME and other methods.

GLOSSARY

Body: The text of an e-mail message. The body of a message follows the header information.

Client: Any application program used to retrieve information from a server. Internet clients include World Wide Web browsers, Usenet newsreaders, and e-mail programs.

Client-server: The relationship between two application programs. One program, the server, is responsible for servicing requests from the other program, the client.

Delivery status notification (DSN): An extended SMTP service that provides information about the delivery status of an e-mail message to the sender.

Disconnected-Resynchronization Mode: A mail-access mode in which mail is synchronized between a server and a client computer. By synchronizing mail on the server, users can access their own mail from any computer that has access to the server where the mail is stored.

Domain name system (DNS): A behind-the-scenes Internet service that translates Internet domain names to their corresponding IP addresses, and vice versa.

E-mail client: An application that runs on a personal computer or workstation and enables the sender to send, receive, and organize e-mail. It is called a client because e-mail systems are based on a client-server architecture. Mail is sent from many clients to a central server, which reroutes the mail to its intended destination.

Encapsulated address: This address provides a way to send the e-mail to a site acting as a gateway for another site while indicating the server to which the message eventually needs to be sent. An encapsulated address consists of an address within an address; the outer address directs the mail to the gateway, which uses the inner address to determine where to send the e-mail. Because the Exchange Internet Mail Service (IMS) uses SMTP as its e-mail protocol, mails sent to an IMS will use encapsulated SMTP as their addressing scheme.

Gateway: Software that translates data from the standards of one system to the standards of another. For example, a gateway might exchange and convert Internet e-mail to X.400 e-mail.

Header: Part of an e-mail message that precedes the body of the message and provides the message originator, date, and time.

Internet message access protocol (IMAP): An Internet protocol used by mail clients for retrieving e-mail messages stored on servers. The latest version, IMAP4, is similar to POP3 but supports some additional features; for example, a user can search through his e-mail messages for key words while the messages are still on mail server. The user can then choose which messages to download to his or her computer. While IMAP-based

applications can operate in offline mode, they typically operate in online or disconnected–resynchronization mode.

Mail access protocol: A standardized set of commands and responses responsible for communication between the mail client and mail server.

Mailbox: A file where e-mail messages are stored.

Mail client: The software used to read, file, send, and otherwise process e-mail, typically running on a user's desktop computer.

Mail delivery agent (MDA): The software that runs mail-delivery processes on the machine where a users' mailbox is located. Often, that delivery is performed directly by the mail transfer agent (MTA), which then serves a secondary role as an MDA. Examples of separate mail delivery agents include Procmail, Deliver, and Cyrdeliver.

Mail relaying: A legitimate practice in which e-mail is routed to an intermediate mail server, which then delivers it to the recipient's mail server. For example, a company can have several servers and one of them is designated as a mail gateway to the Internet. Any e-mail sent to the company would arrive at the gateway server and then be relayed to the appropriate server for delivery to the recipient. Malicious users sometimes try to perform unauthorized mail relaying.

Mail server: A computer typically managed by an ISP or information services department that handles receipt and delivery of e-mail messages. It also may store mail for the user on a temporary or permanent basis.

Mail transfer agent (MTA): The software that is running on a mail server that relays, and delivers mail.

Mail user agent (MUA): The software (also known as the mail client) used to read, file, send, and process e-mail, typically running on a desktop computer.

Multipurpose Internet mail extensions (MIME): An Internet standard that provides the transfer of nontext information, such as sounds and graphics, and non-U.S. English (such as Cyrillic, Chinese, or Japanese) via e-mail.

Network virtual terminal (NVT): A set of facilities for establishing communication by using the TCP/IP protocols

On-demand mail relay (ODMR): A restricted profile of SMTP described in RFC 2645.

Port: In a software device, a port is a specific memory address that is mapped to a virtual networking cable. Ports allow multiple types of traffic to be transmitted to a single IP address. SMTP traditionally uses port 25 for e-mail communication.

Post office protocol (POP): A protocol used to retrieve e-mail from a mail server in offline mode. An e-mail client that implements the POP protocol downloads all new mail from a mail server, terminates the network connection, and processes all mail offline at the client computer. The current version, POP3 can be used with or without SMTP.

Server: A host computer that provides resources to client computers.

Simple mail transfer protocol (SMTP): A protocol widely used to exchange e-mail between e-mail servers on the Internet.

Spam: Undesired junk e-mail or junk postings offering dubious business deals.

User agent (UA): An SMTP component that prepares the message, creates the envelope, and puts the message in the envelope.
